BD Chaufas'id's

HUMAN ANATOMY

Regional and Applied Dissection and Clinical

VOLUME 1 Upper Limb and Thorax

CBS PUBLISHERS & DISTRIBUTORS
NEW DELHI • BANGALORE
Medical knowledge is constantly changing. As new information becomes available, changes in treatment, procedures, equipment and the use of drugs become necessary. The author and the publisher have, as far as it is possible, taken care to ensure that the information given in this text is accurate and up to date. However, readers are strongly advised to confirm that the information, especially with regard to drug usage, complies with the latest legislation and standards of practice.

my teacher
FOURTH EDITION
BD Chaurasia's
Regional and Applied Dissection and Clinical

VOLUME 1
Upper Limb and Thorax

VOLUME 2
Lower Limb, Abdomen and Pelvis

VOLUME 3
Head, Neck and Brain

ABOUT THE EDITOR
Dr. Krishna Garg joined the Department of Anatomy, Lady Hardinge Medical College, New Delhi, in 1964 and learnt and taught anatomy till 1996 except for a brief stint at Maulana Azad Medical College. She has been decorated as Fellow of Indian Medical Association, Academy of Medical Specialists, Member of the Academy of Medical Sciences and Fellow of the International Medical Science Academy. She received the Fika award in 1999 from the Delhi Medical Association and excellence award in Anatomy on Doctors Day in 2004. Krishna Garg is the co-author of Textbook of Histology and Neuroanatomy. Having revised BD Chaurasia's Handbook of General Anatomy in 1996, she has now revised and brought out the 4th edition of the three volumes of BD Chaurasia's Human Anatomy.

This human anatomy is not systemic but regional
Oh yes, it is theoretical as well as practical
Besides the gross features, it is chiefly clinical
Included in anatomy, it is also histological
Anatomy is not only of adult but also embryological
It is concise, comprehensive and clinical
Surface marking is provided in the
to light the instinct of surgeon-in-the-making

Lots of tables for the muscles are provided
even methods for testing are incorporated
Numerous coloured illustrations are added
So that right half of brain gets stimulated
Hope these volumes turn highly useful
The editor's patience and perseverance prove fruitful
Preface to the Fourth Edition

In July 1996, I had gone to the office of CBS Publishers and Distributors to hand over the manuscript of the third edition of our Textbook of Histology, when Mr SK Jain, Managing Director of CBS, requested me to shoulder the responsibility of editing the three volumes of their extremely popular book BD Chaurasia's Human Anatomy, the third edition of which was earlier edited by respected Prof. Inderbir Singh. This was a 'God given gift' which I accepted with great gratitude. This had also been the wishful thinking of my son, now a nephrologist in the US.

The three volumes of the fourth edition of this book are extremely student-friendly. All out efforts have been made to bring them closer to their hearts through serious and subtle efforts. Various ways were thought of, which I discussed with my colleagues and students, and have been incorporated in these volumes.

One significant method suggested was to add 'practical skills' so that these volumes encompass theoretical, practical and clinical aspects of various parts of human body in a functional manner. The paragraphs describing human dissection, printed with blue background, provide necessary instructions for dissection. These entail identifying structures deeper to skin which need to be cut and separated to visualise the anatomic details of various structures.

Dissection means patiently clearing off the fat and fasciae around nerves, blood vessels, muscles, viscera, etc. so that their course, branches and relations are appreciated. This provides the photogenic memory for the 'doctor-in-making'. First year of MBBS course is the only time in life when one can dissect at ease, although it is too early a period to appreciate its value. Good surgeons always refresh their anatomical knowledge before they go to the operation theatre.

Essential part of the text and some diagrams from the first edition have been incorporated glorifying the real author and artist in BD Chaurasia. A number of diagrams on ossification, surface marking, muscle testing, in addition to radiographs, have been added.

The beauty of most of the four-colour figures lies in easy reproducibility in numerous tests and examinations which the reader can master after a few practice sessions only. This makes them user-friendly volumes. Figures are appreciated by the underutilised right half of the cerebral cortex, leaving the dominant left half for other jobs in about 98% of right-handed individuals. At the beginning of each chapter, a few introductory sentences have been added to highlight the importance of the topic covered. A brief account of the related histology and development is put forth so that the given topic is covered in all respects. The entire clinical anatomy has been put with the respective topic, highlighting its importance. The volumes thus are concise, comprehensive and clinically-oriented.

Various components of upper and lower limbs have been described in a tabular form to revise and appreciate their "diversity in similarity". At the end of each section, an appendix has been added wherein the segregated course of the nerves has been aggregated, providing an overview of their entire course. These appendices also contain some clinicoanatomical problems and multiple choice questions to test the knowledge and skills acquired. Prayers, patience and perseverance for almost 8 years have brought out this new edition aimed at providing a holistic view of the amazing structures which constitute the human anatomy.

There are bound to be some errors in these volumes. Suggestions and comments for correction and improvement shall be most welcome: These may please be sent to me through e-mail at cbspubs@del3.vsnl.net.in.

KRISHNA GARG
The necessity of having a simple, systematized J. and complete book on anatomy has long been felt. The urgency for such a book has become all the more acute due to the shorter time now available for teaching anatomy, and also to the falling standards of English language in the majority of our students in India. The national symposium on "Anatomy in Medical Education" held at Delhi in 1978 was a call to change the existing system of teaching the unnecessary minute details to the undergraduate students.

This attempt has been made with an object to meet the requirements of a common medical student. The text has been arranged in small classified parts to make it easier for the students to remember and recall it at will. It is adequately illustrated with simple line diagrams which can be reproduced without any difficulty, and which also help in understanding and memorizing the anatomical facts that appear to defy memory of a common student. The monotony of describing the individual muscles separately, one after the other, has been minimised by writing them out in tabular form, which makes the subject interesting for a lasting memory. The relevant radiological and surface anatomy have been treated in separate chapters. A sincere attempt has been made to deal, wherever required, the clinical applications of the subject. The entire approach is such as to attract and inspire the students for a deeper dive in the subject of anatomy.

The book has been intentionally split in three parts for convenience of handling. This also makes a provision for those who cannot afford to have the whole book at a time.

It is quite possible that there are errors of omission and commission in this mostly single handed attempt. I would be grateful to the readers for their suggestions to improve the book from all angles.

I am very grateful to my teachers and the authors of numerous publications, whose knowledge has been freely utilised in the preparation of this book. I am equally grateful to my professor and colleagues for their encouragement and valuable help. My special thanks are due to my students who made me feel their difficulties, which was a great incentive for writing this book. I have derived maximum inspiration from Prof. Inderbir Singh (Rohtak), and learned the decency of work from Shri SC Gupta (Jiwaji University, Gwalior).

I am deeply indebted to Shri KM Singhal (National Book House, Gwalior) and Mr SK Jain (CBS Publishers and Distributors, Delhi), who have taken unusual pains to get the book printed in its present form. For giving it the desired get-up, Mr VK Jain and Raj Kamal Electric Press are gratefully acknowledged. The cover page was designed by Mr Vasant Paranjpe, the artist and photographer of our college; my sincere thanks are due to him. I acknowledge with affection the domestic assistance of Munne Miyan and the untiring company of my Rani, particularly during the odd hours of this work.

BD CHAURASIA
Acknowledgements

I am grateful to Almighty for giving me the opportunity to edit these three volumes, and further for sustaining the interest which many a times did oscillate.

When I met Mr YN Arjuna, Publishing Director in CBS, in May 2003, light was seen at the end of the tunnel and it was felt that the work on the volumes could begin with definite schedule. He took great interest in going through the manuscript, correcting, modifying and improving wherever necessary. He inducted me to write an introductory paragraph, brief outlines of embryology and histology to make it a concise and complete textbook.

Having retired from Lady Hardinge Medical College within a fortnight of getting this assignment and having joined Santosh Medical College, Ghaziabad, my colleagues there really helped me. I am obliged to Prof. Varsha Katira, Prof. Vishram Singh, Dr Poonam Kharb, Dr Tripta Bhagat (MS Surgery), Dr Nisha Kaul and Ms Jaya. They even did dissection with the steps written for the new edition and modified the text wherever necessary.

From 2000-03, while working at Subharti Medical College, Meerut, the editing of the text continued. Dr Satyam Khare, Associate Professor, suggested me to write the full course of nerves, ganglia, multiple choice questions, etc. with a view to revise the important topics quickly. So, appendices have come up at the end of each section. I am grateful to Prof. AK Asthana, Dr AK Garg and Dr Archana Sharma for helping me when required.

The good wishes of Prof. Mohini Kaul and Prof. Indira Bahl who retired from Maulana Azad Medical College; Director-Prof. Rewa Choudhry, Prof. Sumita Kakar, Prof. Anita Tuli, Prof. Shashi Raheja of Lady Hardinge Medical College; Director-Prof. Vijay Kapoor, Director-Prof. JM Kaul, Director-Prof. Shipra Paul, Prof. RK Suri and Prof. Neelam Vasudeva of Maulana Azad Medical College; Prof. Gayatri Rath of Vardhman Mahavir Medical College; Prof. Ram Prakash, Prof. Veena Bhardwaj, Prof. Kamlesh Khatri, Prof. Jogesh Khanna, Prof. Mahindra Nagar, Prof. Santosh Sanghari of University College of Medical Sciences; Prof. Kiran Kucheria, Prof. Rani Kumar, Prof. Shashi Wadhwa, Prof. Usha Sabherwal, and Prof. Raj Mehra of All India Institute of Medical Sciences and all my colleagues who have helped me sail through the dilemma.

I am obliged to Prof. DR Singh, Ex-Head, Department of Anatomy, KGMC, Lucknow, for his constructive guidance and Dr MS Bhatia, Head, Department of Psychiatry, UCMS, Delhi, who suggested the addition of related histology.

It is my pleasure to acknowledge Prof. Mahdi Hasan, Ex-Prof. & Head, Department of Anatomy, and Principal, JN Medical College, Aligarh; Prof. Veena Sood and Dr Poonam Singh of DMC, Ludhiana; Prof. S Lakshmanan, Rajah Muthiah Medical College, Tamil Nadu; Prof. Usha Dhall and Dr Sudha Chhabra, Pt. BD Sharma PGIMS, Rohtak; Prof. Ashok Sahai, KG Medical College, Lucknow; Prof. Balbir Singh, Govt. Medical College, Chandigarh; Prof. Asha Singh, Ex-Prof. & Head, MAMC, New Delhi; Prof. Vasundhara Kulshreshtha, SN Medical College, Agra; and Dr Brijendra Singh, Head, Department of Anatomy, ITS Centre for Dental Science and Research, Muradnagar, UP, for inspiring me to edit these volumes.

I am obliged to my mother-in-law and my mother whose blessings have gone a long way in the completion of this arduous task. My sincere thanks are due to my husband Dr DP Garg, our children Manoj and Rekha, Manish and Shilpa, and the grandchildren, who challenged me at times but supported me all the while. The cooperation extended by Rekha is much appreciated.

I am deeply indebted to Mr SK Jain Managing Director of CBS, Mr VK Jain, Production Director, Mr BM Singh and their team for their keen interest and all out efforts in getting the volumes published.

I am thankful to Mr Ashok Kumar who has skillfully painted black and white volumes into coloured volumes to enhance clarity. Ms Deepti Jain, Ms Anupam Jain and Ms Parul Jain have carried out the corrections very diligently. Lastly, the job of pagination came on the shoulders of Mr Karzan Lai Prashar who has left no stone unturned in doing his job perfectly.

Last, but not the least, the spelling mistakes have been corrected by my students, especially Ms Ruchika Girdhar and Ms Hina Garg of 1st year Bachelor of Physiotherapy course at Banarsedas Chandiwala Institute of Physiotherapy, New Delhi, and Mr Ashutosh Gupta of 1st Year BDS at ITS Centre for Dental Science and Research, Muradnagar.

May Almighty inspire all those who study these volumes to learn and appreciate CLINICAL ANATOMY and DISSECTION and be happy and successful in their lives.

KRISHNA GARG

Section 1

LIMB
Mie fore and hind limbs were evolved basically for bearing the weight of the body and for locomotion as is seen in quadrupeds, for example cows or dogs. The two pairs of limbs are, therefore, built on the same basic principle.

Each limb is made up of a basal segment or girdle, and a free part divided into proximal, middle and distal segments. The girdle attaches the limb to the axial skeleton. The distal segment carries the five digits (Table 1.1).

However, with the evolution of the erect posture in man, the function of weight-bearing was taken over by the lower limbs. Thus the upper limbs, especially the hands became free and gradually evolved into organs having great manipulative skills.

This has become possible because of a wide range of mobility at the shoulder. The whole upper limb works as a jointed lever. The human hand is a grasping tool. It is exquisitely adaptable to perform various complex functions under the control of the brain. The unique position of man as a master mechanic of the animal world is because of the skilled movements of his hands.

### Parts of the Upper Limb

We have seen that the upper limb is made up of four parts: (1) shoulder; (2) arm or brachium; (3) forearm or antebrachium; and (4) hand or manus. Further subdivisions of these parts are given below. Also see Table 1.2 and Fig. 1.1.

1. The **shoulder region** includes: (a) the *pectoral* or *breast region* on the front of the chest; (b) the *axilla* or *armpit*; and (c) the *scapular region* on the back comprising parts around the scapula. The bones of the shoulder girdle are the clavicle and the scapula. Of these only the clavicle articulates with the axial skeleton at the sternoclavicular joint. The bones of the shoulder girdle articulate with each other at the acromioclavicular joint.

2. The arm (upper arm or brachium) extends from the shoulder to the elbow (or cubitus). The bone of the arm is the humerus. Its upper end meets the scapula and forms the shoulder joint. The shoulder joint permits movements of the arm.

3. The **forearm** (antebrachium) extends from the elbow to the wrist. The bones of the forearm are the radius and the ulna. At their upper ends they meet the lower end of the humerus to form the elbow joint. Their lower ends meet the carpal bones to form the wrist joint. The radius and ulna meet each other at the radioulnar joints.

   The elbow joint permits movements of the forearm, namely flexion and extension. The radioulnar joints permit rotatory movements of the forearm called pronation and supination. In a midflexed elbow, the palm faces upwards in supination and downwards in pronation. During the last movement the radius rotates around the ulna.

4. The **hand (manus)** includes: (a) the *wrist* or *carpus*, supported by eight carpal bones arranged in two rows; (b) the *hand proper* or metacarpus, supported by five metacarpal bones; and (c) five *digits*

(thumb and four fingers). Each finger is supported by three phalanges, but the thumb has only two phalanges (there being 14 phalanges in all). The carpal bones form the wrist joint with the radius, intercarpal joints with one another, and carpometacarpal joints with the metacarpals. The phalanges form metacarpophalangeal joints with the metacarpals and interphalangeal joints with one another. Movements of the hand are permitted chiefly at the wrist joint: the thumb moves at the first carpometacarpal joint; and each finger at its metacarpophalangeal joint. Figure 1.2 shows the lines of force transmission.

Evolution of Upper Limbs

The forelimbs have evolved from the pectoral fins of fishes. In tetrapods (terrestrial vertebrates), all the four limbs are used for supporting body weight, and for locomotion. In arboreal (tree dwelling) human ancestors, the forelimbs have been set free from their weight-bearing function. The forelimbs, thus 'emancipated', acquired a wide range of mobility and were used forprehension or grasping, feeling, picking, holding, sorting, breaking, fighting, etc. These functions became possible only after necessary structural modifications such as: (a) appearance of joints permitting rotatory movements of the forearms (described as supination and pronation), as a result of which food could be picked up and taken to the mouth; (b) addition of the clavicle, which has evolved with the function ofprehension; (c) rotation of the thumb through 90 degrees, so that it can be opposed to other fingers for grasping; and (d) appropriate changes for free mobility of the fingers and hand. The primitive pentadactyl limb of amphibians, terminating in five digits, has persisted through evolution and is seen in man. In some other species, however, the limbs are altogether lost, as in snakes; while in others the digits are reduced in number as in ungulates. The habit of brachiation, i.e. suspending the body by the arms, in anthropoid apes resulted in disproportionate lengthening of the forearms, and also in elongation of the palm of fingers. Some further details of the evolution of the upper limb will be taken up in appropriate sections.

Study of Anatomy

In studying the anatomy of any region (by dissection), it is usual to begin by studying any peculiarities of the skin, the superficial fascia and its contents, and the deep fascia. This is followed by the study of the muscles of the region, and finally, the blood vessels and nerves. This pattern is followed in the descriptions of various regions. These descriptions
Fig. 1.1: Parts of the upper limb.

Carpal bones (8)

Metacarpal bones (5)
Phalanges (14)

Phalanges (14)
should be read only after the part has been dissected with the help of the steps of dissection provided in the book.

Before undertaking the study of any part of the body, it is essential for the student to acquire some knowledge of the bones of the region. It is for this reason that a chapter on bones (osteology) is given at the beginning of each section. While reading this chapter, the students should palpate the various parts of bones on themselves. They must possess set of loose bones for study, and for marking the attachments of muscles and ligaments.
Out of 206 total bones in man, the upper limbs contain as many as 64 bones. Each side consists of 32 bones, the distribution of which is shown in Table 2.1. The individual bones of the upper limb will be described one by one. Their features and attachments should be read before undertaking the dissection of the part concerned. The paragraphs on attachments should be revised when the dissection of a particular region has been completed.

**THE CLAVICLE**

The clavicle is a long bone (Figs 2.1-2.3). It supports the shoulder so that the arm can swing clearly away from the trunk. The clavicle transmits the weight of the limb to the sternum. The bone has a cylindrical part called the shaft, and two ends, lateral and medial.

**The Shan**

The shaft (Figs 2.1, 2.2) is divisible into the lateral one-third and the medial two-thirds.

- **The lateral one-third of the shaft** is flattened from above downwards. It has two borders, anterior and posterior. The anterior border is concave forwards. The posterior border is convex backwards. This part of the bone has two surfaces, superior and inferior. The superior surface is subcutaneous and the inferior surface presents an elevation called the conoid tubercle and a ridge called the trapezoid ridge.

- **The medial two-thirds of the shaft** is rounded and is said to have four surfaces. The anterior surface is convex forwards. The posterior surface is smooth. The superior surface is rough in its medial part. The inferior surface has a rough oval impression at the medial end. The lateral half of this surface has a longitudinal subclavian groove. The nutrient foramen lies at the lateral end of the groove.

**Lateral and Medial Ends**

1. The lateral or acromial end is flattened from above downwards. It bears a facet that articulates with the acromion process of the scapula to form the acromioclavicular joint.
2. The medial or sternal end is quadrangular and articulates with the clavicular notch of the manubrium sterni to form the sternoclavicular joint. The articular surface extends to the inferior aspect, for articulation with the first costal cartilage.

**Side Determination**

The side to which a clavicle belongs can be determined from the following characters:

1. The lateral end is flat, and the medial end is large and quadrilateral.
2. The shaft is slightly curved, so that it is convex forwards in its medial two-thirds, and concave forwards in its lateral one-third.
3. The inferior surface is grooved longitudinally in its middle one-third.

**Peculiarities of the Clavicle**

1. It is the only long bone that lies horizontally.
2. It is subcutaneous throughout.
3. It is the first bone to start ossifying.
4. It is the only long bone which ossifies in membrane.
5. It is the only long bone which has two primary centres of ossification.
6. It is generally said to have no medullary cavity, but this is not always true.
7. It is occasionally pierced by the middle supraclavicular nerve.
**Sex Determination**

1. In females, the clavicle is shorter, lighter, thinner, smoother, and less curved than in males.
2. The midshaft circumference and the weight of the clavicle are reliable criteria for sexing the clavicle.
3. In females, the lateral end of the clavicle is a little below the medial end; in males, the lateral end is either at the same level or slightly higher than the medial end.

**Morphology of the Clavicle**

See morphology of shoulder girdle following description of scapula (Page-14).

**ATTACHMENTS ON THE CLAVICLE**

1. *At the lateral end* the margin of the articular surface for the acromioclavicular joint gives attachment to the joint capsule.
2. *At the medial end* the margin of the articular surface for the sternum gives attachment to: (a) the fibrous capsule all round; (b) the articular disc posterosuperiorly; and (c) the interclavicular ligament superiorly (Fig. 2.4).
3. *Lateral one-third of shaft*
   - (a) The anterior border gives origin to the **deltoid** (Figs 2.3A and 2.3B).
   - (b) The posterior border provides insertion to the **trapezius** (Fig. 5.4).
(c) The conoid tubercle and trapezoid ridge give attachment to the conoid and trapezoid parts of the coracoclavicular ligament (Fig. 2.4).

4. **Medial two-thirds of the shaft**
   (a) The anterior surface gives origin to the pectoralis major (Fig. 4.2).
   (b) The rough superior surface gives origin to the clavicular head of the sternocleidomastoid.
   (c) The oval impression on the inferior surface at the medial end gives attachment to the costoclavicular ligament.
   (d) The subclavian groove gives insertion to the subclavius muscle. The margins of the groove give attachment to the clavipectoral fascia (Fig. 4.2).

The nutrient foramen transmits a branch of the suprascapular artery.

**Fig. 2.4: The sternoclavicular and acromioclavicular joints.**

**Ossification:** The clavicle is the first bone in the body to ossify (Fig. 2.5). Except for its medial end, it ossifies in membrane. It ossifies from two primary centres and one secondary centre.

The two primary centres appear in the shaft between the fifth and sixth weeks of intrauterine life, and fuse about the 45th day. The secondary centre for the medial end appears during 15-17 years, and fuses with the shaft during 21-22 years. Occasionally there may be a secondary centre for the acromial end.

**CLINICAL ANATOMY**

The clavicle is commonly fractured by falling on the outstretched hand (indirect violence). The most common site of fracture is the junction between the two curvatures of the bone, which is the weakest point. The lateral fragment is displaced downwards by the weight of the limb.

The clavicles may be congenitally absent, or imperfectly developed in a disease called cleidocranial dysostosis. In this condition, the shoulders droop, and can be approximated anteriorly in front of the chest.

The scapula is a thin bone placed on the posterolateral aspect of the thoracic cage. The scapula has two surfaces, three borders, three angles, and three processes (Fig. 2.6).

**The Surfaces**

1. The **costal surface** or subscapular fossa is concave and is directed medially and forwards. It is marked by three longitudinal ridges. Another thick ridge adjoins the lateral border. This part of the bone is almost rod-like: It acts as a lever for the action of the **serratus anterior** in overhead abduction of the arm.
2. The **dorsal surface** gives attachment to the spine of the scapula which divides the surface into a smaller **supraspinous fossa** and a larger **infraspinous fossa**. The two fossae are connected by the spinoglenoid notch, situated lateral to the root of the spine.

**The Borders**

1. The **superior border** is thin and shorter. Near the root of the coracoid process it presents the **suprascapular notch**.
2. The **lateral border** is thick. At the upper end it presents the **infraglenoid tubercle**.

**Fig. 2.5: Ossification.**

---

1. The **costal surface** or subscapular fossa is concave and is directed medially and forwards. It is marked by three longitudinal ridges. Another thick ridge adjoins the lateral border. This part of the bone is almost rod-like: It acts as a lever for the action of the **serratus anterior** in overhead abduction of the arm.
2. The **dorsal surface** gives attachment to the spine of the scapula which divides the surface into a smaller **supraspinous fossa** and a larger **infraspinous fossa**. The two fossae are connected by the spinoglenoid notch, situated lateral to the root of the spine.

**The Borders**

1. The **superior border** is thin and shorter. Near the root of the coracoid process it presents the **suprascapular notch**.
2. The **lateral border** is thick. At the upper end it presents the **infraglenoid tubercle**.
3. The medial border is thin. It extends from the superior angle to the inferior angle.

The Angles

1. The superior angle is covered by the trapezius.
2. The inferior angle is covered by the latissimus dorsi. It moves forwards round the chest when the arm is abducted.
3. The lateral or glenoid angle is broad and bears the glenoid cavity or fossa, which is directed forwards, laterally and slightly upwards.

The Processes

1. The spine or spinous process is a triangular plate of bone with three borders and two surfaces. It divides the dorsal surface of the scapula into the
supraspinous and infraspinous fossae. Its posterior border is called the *crest of the spine*. The crest has upper and lower lips.

1. The *acromion* has two borders, medial and lateral; two surfaces, superior and inferior; and a facet for the clavicle (Fig. 2.7).

2. The *coracoid* process is directed forwards and slightly laterally.

**Side Determination**

1. The lateral or glenoid angle is large and bears the glenoid cavity.

2. The dorsal surface is convex and is divided by the triangular spine into the supraspinous and infraspinous fossae. The costal surface is concave to fit on the convex chest wall.

3. The lateral thickest border runs from the glenoid cavity above to the inferior angle below.
Fig. 2.7: General features of right scapula and humerus: Posterior view.
Muscles

1. The multipennate *subscapularis* arises from the medial two-thirds of the subscapular fossa (Figs 2.8, 7.4).
2. The *supraspinatus* arises from the medial two-thirds of the supraspinous fossa including the upper surface of the spine (Fig. 7.3).
3. The *infraspinatus* arises from the medial two-thirds of the infraspinous fossa, including the lower surface of the spine (Fig. 2.9).
4. The *deltoid* arises from the lower border of the crest of the spine and from the lateral border of the acromion (Fig. 2.10). The acromial fibres are multipennate.
1. The trapezius is inserted into the upper border of the crest of the spine and into the medial border of the acromion (Figs 2.9, 2.10).

2. The serratus anterior is inserted along the medial border of the costal surface: one digitation from the superior angle to the root of spine, two digitations to the medial border, and five digitations to the inferior angle (Figs 2.12-2.14).

3. The longhead of the biceps brachii arises from the supraglenoid tubercle; and the short head from the lateral part of the tip of the coracoid process (Fig. 8.3).

4. The coracobrachialis arises from the medial part of the tip of the coracoid process.

5. The pectoralis minor is inserted into the medial border and superior surface of the coracoid process.
Fig. 2.9: Right scapula: Dorsal aspect.
1. The *long head of the triceps* arises from the infraglenoid tubercle.

2. The teres *minor* arises from the upper two-thirds of the rough strip on the dorsal surface along the lateral border.
1. The teres *major* arises from the lower one-third of the rough strip on the dorsal aspect of the lateral border.
2. The *levator scapulae* is inserted along the dorsal aspect of the medial border, from the superior angle up to the root of the spine.
Supraspinatus

Fig. 2.10: Right scapula: Superior aspect.
14. The *rhomboideus minor* is inserted into the medial border (dorsal aspect) opposite the root of the spine.

1. The *rhomboideus major* is inserted into the medial border (dorsal aspect) between the root of the spine and the inferior angle.
2. The *inferior belly of the omohyoid* arises from the upper border near the suprascapular notch.

**Ligaments**

1. The margin of the glenoid cavity gives attachment to the capsule of the shoulder joint and to the *glenoidal labrum* (Fig. 10.4).
2. The margin of the facet on the medial aspect of the acromion gives attachment to the capsule of the acromioclavicular joint.
1. The coracoacromial ligament is attached: (a) to the lateral border of the coracoid process, and (b) to the medial side of the tip of the acromion process (Figs 2.10, 7.8, 10.4).
2. The coracohumeral ligament is attached to the root of the coracoid process.
3. The coracoclavicular ligament is attached to the coracoid process: the trapezoid part on the superior aspect, and the conoid part near the root.
4. The suprascapular ligament bridges across the suprascapular notch and converts it into a foramen which transmits the suprascapular nerve. The suprascapular vessels lie above the ligament (Fig. 10.3).
5. The spinoglenoid ligament bridges the spinoglenoid notch. The suprascapular vessels and nerve pass deep to it (Fig. 10.3).

Fig. 2.14: Diagram showing relation of serratus anterior to chest wall and subscapularis.

**Ossification:** The scapula ossifies from one primary centre and seven secondary centres. The primary centre appears near the glenoid cavity during the eighth week of development. The first secondary centre appears in the middle of the coracoid process during the first year and fuses by the 15th year. The subcoracoid centre appears in the root of the coracoid process during the 10th year and fuses by the 16th to 18th years (Fig. 2.15). The other centres,
including two for the acromion, one for the lower two-thirds of the margin of the glenoid cavity, one for the medial border and one for the inferior angle, appear at puberty and fuse by the 25th year.

The fact of practical importance is concerned with the acromion. If the two centres appearing for acromion fail to unite, it may be interpreted as a fracture on radiological examination. In such cases a radiograph of the opposite acromion will mostly reveal similar failure of union.

**CLINICAL ANATOMY**

1. Paralysis of the serratus anterior causes 'winging' of the scapula. The medial border of the bone becomes unduly prominent, and the arm cannot be abducted beyond 90 degrees.

2. In a developmental anomaly called *scaphoid scapula*, the medial border is concave.

*Morphology of the Shoulder Girdle*

The shoulder girdle of man has evolved from that of primitive animals. The girdle of the duckbill (a primitive egg-laying mammal) and that of primitive reptiles are alike. This basic form appears to be the precursor of the various types of mammalian shoulder girdles. The primary reptilian girdle is divisible into a dorsal and a ventral element. The dorsal element of the girdle arch consists of the *scapula*. The ventral element of the girdle arch is more complex and is made up of a posterior part, the *coracoid*, and an anterior part, the *precoracoid*. Both components of the ventral element articulate ventrally with the sternum. The dorsal end of the coracoid helps the scapula in forming the glenoid cavity. In the duckbill, the coracoid is represented by two bones, the coracoid and the *epicoracoid*.

In man, and all higher mammals, where the upper limbs are freely mobile, the coracoid element is much reduced in size to form the coracoid process which fuses with the scapula. The costocoracoid ligament may be a derivative of the ventral part of the coracoid element. The precoracoid has been partly or entirely replaced in all mammals by the clavicle, which is the sole mammalian survivor of a considerable variety of dermal elements (like cleithrum and interclavicle) present in the pectoral girdles of lower vertebrates. The interclavicle is represented in man by the inter-clavicular ligament. The epicoracoid of the duckbill corresponds to the occasional suprasternal ossicles of man. Recalling the homologous parts, the shoulder and hip girdles, it may be noted that (a) the scapula corresponds to the ilium; (b) the coracoid to the ischium; and (c) the precoracoid to the pubis.
THE HUMERUS

The humerus is the bone of the arm. It is the longest bone of the upper limb. It has an upper end, a lower end and a shaft (Figs 2.6, 2.7).

The Upper End

1. The head is directed medially, backwards and upwards. It articulates with the glenoid cavity of the scapula to form the shoulder joint. The head forms about one-third of a sphere and is much larger than the glenoid cavity.
2. The line separating the head from the rest of the upper end is called the anatomical neck.
3. The lesser tubercle is an elevation on the anterior aspect of the upper end.
4. The greater tubercle is an elevation that forms the lateral part of the upper end. Its posterior aspect is marked by three impressions—upper, middle and lower.
5. The intertubercular sulcus or bicipital groove separates the lesser tubercle medially from the anterior part of the greater tubercle. The sulcus has medial and lateral lips that represent downward prolongations of the lesser and greater tubercles.
6. The narrow line separating the upper end of the humerus from the shaft is called the surgical neck.

The Shaft

The shaft is rounded in the upper half and triangular in the lower half. It has three borders and three surfaces.

Borders

1. The upper one-third of the anterior border forms the lateral lip of the intertubercular sulcus. In its middle part, it forms the anterior margin of the deltoid tuberosity. The lower half of the anterior border is smooth and rounded.
2. The lateral border is prominent only at the lower end where it forms the lateral supracondylar ridge. In the upper part, it is barely traceable up to the posterior surface of the greater tubercle. In the middle part, it is interrupted by the radial or spiral groove.
3. The upper part of the medial border forms the medial lip of the intertubercular sulcus. About its middle it presents a rough strip. It is continuous below with the medial supracondylar ridge.

Surfaces

1. The anterolateral surface lies between the anterior and lateral borders. The upper half of this surface is covered by the deltoid. A little above the middle it is marked by a V-shaped deltoid tuberosity. Behind the deltoid tuberosity the radial groove runs downwards and forwards across the surface.
   1. The anteromedial surface lies between the anterior and medial borders. Its upper one-third is narrow and forms the floor of the intertubercular sulcus. A nutrient foramen is seen on this surface near its middle, near the medial border.
   2. The posterior surface lies between the medial and lateral borders. Its upper part is marked by an oblique ridge. The middle one-third is crossed by the radial groove.

The Lower End

The lower end of the humerus forms the condyle which is expanded from side to side, and has articular and non-articular parts. The articular part includes the following.

1. The capitulum is a rounded projection which articulates with the head of the radius (Fig. 2.6).
2. The trochlea is a pulley-shaped surface. It articulates with the trochlear notch of the ulna. The medial edge of the trochlea projects down 6 mm more than the lateral edge: this results in the formation of the carrying angle.

The non-articular part includes the following.

1. The medial epicondyle is a prominent bony projection on the medial side of the lower end. It is subcutaneous and is easily felt on the medial side of the elbow.
2. The lateral epicondyle is smaller than the medial epicondyle. Its anterolateral part has a muscular impression.
3. The sharp lateral margin just above the lower end is called the lateral supracondylar ridge.
4. The medial supracondylar ridge is a similar ridge on the medial side.
5. The coronoid fossa is a depression just above the anterior aspect of the trochlea. It accommodates the coronoid process of the ulna when the elbow is flexed.
6. The radial fossa is a depression present just above the anterior aspect of the capitulum. It accommodates the head of the radius when the elbow is flexed.
7. The olecranon fossa lies just above the posterior aspect of the trochlea. It accommodates the olecranon process of the ulna when the elbow is extended.

Side Determination

1. The upper end is rounded to form the head. The lower end is expanded from side to side and flattened from before backwards.
1. The head is directed medially and backwards.
2. The lesser tubercle projects from the front of the upper end and is limited laterally by the intertubercular sulcus or bicipital groove.

**ATTACHMENTS ON THE HUMERUS**

1. The multipennate *subscapularis* is inserted into the lesser tubercle (Fig. 2.16).
2. The *supraspinatus* is inserted into the uppermost impression on the greater tubercle.
3. The *infraspinatus* is inserted into the middle impression on the greater tubercle.
4. The teres minor is inserted into the lower lip of the intertubercular sulcus. The insertion is bilaminar.
5. The *pectoralis major* is inserted into the lateral lip of the intertubercular sulcus. The insertion is bilaminar.

---

**Fig. 2.16: Right humerus seen from front.**

**Fig. 2.17: Right humerus seen from behind.**
1. The latissimus dorsi is inserted into the floor of the intertubercular sulcus.
2. The teres major is inserted into the medial lip of the intertubercular sulcus.
3. The contents of the intertubercular sulcus are: (a) the tendon of the long head of the biceps, and its synovial sheath; and (ii) the ascending branch of the anterior circumflex humeral artery.
4. The deltoid is inserted into the deltoid tuberosity.
5. The coracobrachialis is inserted into the rough area on the middle of the medial border.
6. The brachialis arises from the lower halves of the anteromedial and anterolateral surfaces of the shaft. Part of the area extends on to the posterior aspect (Fig. 8.5).
7. The brachioradialis arises from the upper two-thirds of the lateral supracondylar ridge.
8. The extensor carpi radialis longus arises from the lower one-third of the lateral supracondylar ridge (Figs 2.18, 9.44).
9. The pronator teres (humeral head) arises from the lower one-third of the medial supracondylar ridge.
10. The superficial flexor muscles of the forearm arise by a common origin from the anterior aspect of the medial epicondyle. This is called the common flexor origin.
11. The superficial extensor muscles of the forearm have a common origin from the lateral epicondyle. This is called the common extensor origin (Fig. 2.18).
12. The anconeus arises from the posterior surface of the lateral epicondyle.
13. Lateral head of triceps brachii arises from oblique ridge on the upper part of posterior surface above the radial groove, while its medial head arises from posterior surface below the radial groove (Fig. 2.17).
14. The capsular ligament of the shoulder joint is attached to the anatomical neck except on the medial side where the line of attachment dips down by about two centimetres to include a small area of the shaft within the joint cavity. The line is interrupted at the intertubercular sulcus to provide an aperture through which the tendon of the long head of the biceps leaves the joint cavity.
15. The capsular ligament of the elbow joint is attached to the lower end along a line that reaches the upper limits of the radial and coronoid fossae, anteriorly; and of the olecranon fossa posteriorly; so that these fossae lie within the joint cavity. Medially the line of attachment passes between the medial epicondyle and the trochlea. On the lateral side it passes between the lateral epicondyle and the capitulum.

**Ossification:** The humerus ossifies from one primary centre and 7 secondary centres. The primary centre appears in the middle of the diaphysis during the 8th week of development (Table 2.1).
The upper end ossifies from 3 secondary centres: one for the head (first year), one for the greater tubercle (second year), and one for the lesser tubercle (fifth year). The 3 centres fuse together during the sixth year to form one epiphysis, which fuses with the shaft during the 20th year. The epiphyseal line encircles the bone at the level of the lowest margin of the head. This is the growing end of the bone (remember that the nutrient foramen is always directed away from the growing end).

The lower end ossifies from 4 centres which form 2 epiphyses. The centres include: one for the capitulum and the lateral flange of the trochlea (first year), one for the medial flange of the trochlea (9th year), and one for the lateral epicondyle (12th year): all three fuse during the 14th year to form one epiphysis, which fuses with the shaft at about 16 years. The centre for the medial epicondyle appears during 4-6 years, forms a separate epiphysis, and fuses with the shaft during the 20th years.

**Axillary**

1. Three nerves are directly related to the humerus and are, therefore, liable to injury: the axillary at the surgical neck, the radial at the radial groove, and the ulnar behind the medial epicondyle (Fig. 2.19).

2. The common sites of fracture are the surgical neck, the shaft, and the supracondylar region.

*Supracondylar fracture* is common in young age. It is produced by a fall on the outstretched hand. The lower fragment is mostly displaced backwards, so that the elbow is unduly prominent, as in dislocation of the elbow joint. However, in fracture, the three bony points of the elbow form the usual equilateral triangle. This fracture may cause injury to the median nerve. It may also lead to Volkmann's ischaemic contracture, and myositis ossificans.

1. The humerus has a poor blood supply at the junction of its upper and middle thirds. Fractures at this site show delayed union or non-union.

2. The head of the humerus commonly dislocates inferiorly.

The radius is the lateral bone of the forearm, and is homologous with the tibia of the lower limb. It has an upper end, a lower end and a shaft.
The Upper End

1. The head is disc-shaped and is covered with hyaline cartilage (Figs 2.20, 2.21). It has a superior concave surface which articulates with the capitulum of the humerus at the elbow joint. The circumference of the head is also articular. It fits into a socket formed by the radial notch of the ulna and the annular ligament, thus forming the superior radioulnar joint.

2. The neck is enclosed by the narrow lower margin of the annular ligament. The head and neck are free from capsular attachment and can rotate freely within the socket.

3. The tuberosity lies just below the medial part of the neck. It has a rough posterior part and a smooth anterior part.

The Shaft

It has three borders and three surfaces.

Borders

1. The anterior border extends from the anterior margin of the radial tuberosity to the styloid process. It is oblique in the upper half of the shaft, and vertical in the lower half. The oblique part is called the anterior oblique line. The lower vertical part is crest-like (Fig. 2.22).

2. The posterior border is the mirror image of the anterior border, but is clearly defined only in its
middle one-third. The upper oblique part is known as the posterior oblique line (Fig. 2.23).

3. The medial or interosseous border is the sharpest of the three borders. It extends from the radial tuberosity above to the posterior margin of the ulnar notch below. The interosseous membrane is attached to its lower three-fourths. In its lower part, it forms the posterior margin of an elongated triangular area.

**Surfaces**

1. The anterior surface lies between the anterior and interosseous borders. A nutrient foramen opens in its upper part, and is directed upwards. The nutrient artery is a branch of the anterior interosseous artery.
1. The posterior surface lies between the posterior and interosseous borders.
2. The lateral surface lies between the anterior and posterior borders.

The Lower End

The lower end is the widest part of the bone. It has 5 surfaces (Fig. 2.24).
1. The anterior surface is in the form of a thick prominent ridge. The radial artery is palpated against this surface.
2. The posterior surface presents four grooves for the extensor tendons. The dorsal tubercle (of Lister) lies lateral to an oblique groove.
3. The medial surface is occupied by the ulnar notch for the head of the ulna.
4. The lateral surface is prolonged downwards to form the styloid process.
5. The inferior surface bears a triangular area for the scaphoid bone, and a medial quadrangular area for the lunate bone. This surface takes part in forming the wrist joint.

Side Determination

The smaller circular and upper end is concave followed by a constricted neck. Just below the medial aspect of neck is the radial tuberosity.

The wider lower end is thick with a pointed styloid process on its lateral aspect and a prominent dorsal tubercle on its posterior surface. Medial or interosseous border is thin and sharp.
ATTACHMENTS ON THE RADIUS

1. The *biceps brachii* is inserted into the rough posterior part of the radial tuberosity. The anterior part of the tuberosity is covered by a bursa (Fig. 2.25).
2. The *supinatoris* inserted into the upper part of the lateral surface (Fig. 2.26).
The pronator teres is inserted into the middle of the lateral surface.

The brachioradialis is inserted into the lowest part of the lateral surface just above the styloid process.

The radial head of the flexor digitorum superficialis takes origin from the anterior oblique line or the upper part of anterior border (Fig. 2.27).

1. The flexor pollicis longus takes origin from the upper two-thirds of the anterior surface (Fig. 2.27).

2. The pronator quadratus is inserted into the lower part of the anterior surface and into the triangular area on the medial side of the lower end. The radial artery is palpated as "radial pulse" as it lies on the lower part of anterior surface of radius, lateral to the tendon of flexor carpi radialis (Fig. 9.11).

3. The abductor pollicis longus and the extensor pollicis brevis arise from the posterior surface.

4. The quadrateligamentis attached to the medial part of the neck.

1. The oblique cord is attached on the medial side just below the radial tuberosity.

2. The articular capsule of the wrist joint is attached to the anterior and posterior margins of the inferior articular surface.

3. The articular disc of the inferior radioulnar joint is attached to the lower border of the ulnar notch.

4. The extensor retinaculum is attached to the lower part of the anterior border.

5. The interosseous membrane is attached to the lower three-fourths of the interosseous border.

Ossification: The shaft ossifies from a primary centre which appears during the 8th week of development. The lower end ossifies from a secondary centre which appears during the first year and fuses at 20 years; it is the growing end of the bone. The upper end (head) ossifies from a secondary centre which appears during the 4th year and fuses at 18 years (Table 2.1).

CLINICAL ANATOMY

1. The radius commonly gets fractured about 2 cm above its lower end (Colles's fracture). This fracture is caused by a fall on the outstretched hand. The distal fragment is displaced upwards and backwards, and the radial styloid process comes to lie proximal to the ulnar styloid process. (It normally lies distal to the ulnar styloid process.)

2. Smith's fracture is the reverse of the Colles' fracture, the distal segment being palmar flexed rather than dorsiflexed. It is uncommon, and is produced by a fall on the dorsum of a palmar flexed hand.

3. Congenital absence of the radius is a rare anomaly. This results in gross radial deviation of the hand, and the thumb is often absent.

4. Radioulnar synostosis is also a rare condition in which the radius and ulna are fused.
together, usually in the proximal 2.5 cm of the bone. Pronation and supination is impossible in these cases.

5. A sudden powerful jerk on the hand of a child may dislodge the head of the radius from the grip of the annular ligament. This is known as subluxation of the head of the radius. The head can normally be felt in a hollow behind the lateral epicondyle of the humerus.

THE ULNA

The ulna is the medial bone of the forearm, and is homologous with the fibula of the lower limb. It has upper end, lower end, and a shaft.

The Upper End

The upper end presents the olecranon and coronoid processes, and the trochlear and radial notches (Figs 2.20, 2.21).

Fig. 2.26: Right radius and ulna: Posterior aspect
1. The **olecranon process** projects upwards from the shaft. It has superior, anterior, posterior, medial and lateral surfaces. The *anterior surface* is articular: it forms the upper part of the trochlear notch. The *posterior surface* forms a triangular subcutaneous area which is separated from the skin by a *bursa*. Inferiorly it is continuous with the posterior border of the shaft of the ulna. The upper part forms the point of the elbow. The *medial surface* is continuous inferiorly with the posterior surface of the shaft.

2. The **coronoid process** projects forwards from the shaft just below the olecranon and has four surfaces: superior, anterior, medial and lateral. The *superior surface* forms the lower part of the trochlear notch. The *anterior surface* is triangular and rough. Its lower corner forms the ulnar tuberosity. The upper part of its lateral surface is marked by the radial notch for the head of the radius. The annular ligament is attached to the anterior and posterior margins of the notch. The lower part of the lateral surface forms a depressed area to accommodate the radial tuberosity. It is limited behind by a ridge called the supinator crest.
1. The *trochlear notch* forms an articular surface that articulates with the trochlea of the humerus to form the elbow joint.
2. The *radial notch* articulates with the head of the radius to form the superior radioulnar joint.

The Shaft
The shaft has three borders and three surfaces (Fig. 2.22).

Borders
1. The *interosseous or lateral* border is sharpest in its middle two-fourths. Inferiorly, it can be traced to the lateral side of the head. Superiorly, it is continuous with the supinator crest.
2. The *anterior border* is thick and rounded. It begins above on the medial side of the ulnar tuberosity, passes backwards in its lower one-third, and terminates at the medial side of the styloid process.
3. The *posterior border* is subcutaneous. It begins, above, at the apex of the triangular subcutane-
ous area at the back of the olecranon, and terminates at the base of the styloid process.

**Surfaces**

1. The *anterior surface* lies between the anterior and interosseous borders. A nutrient foramen is seen on the upper part of this surface. It is directed upwards. The nutrient artery is derived from the anterior interosseous artery.
2. The *medial surface* lies between the anterior and posterior borders.
3. The *posterior surface* lies between the posterior and interosseous borders. It is subdivided into three areas by two lines. An oblique line divides it into upper and lower parts. The lower part is further divided by a vertical line into a medial and a lateral area.

**The Lower End**

The lower end is made up of the head and the styloid process. The head articulates with the ulnar notch of the radius to form the inferior radioulnar joint. It is separated from the wrist joint by the articular disc (Figs 2.23, 2.24). Ulnar artery and nerve lie on the anterior aspect of head of ulna (Fig. 2.28).

The styloid process projects downwards from the posteromedial side of the lower end of the ulna. Posteriorly, between the head and the styloid process there is groove for the tendon of the extensor carpi ulnaris.

**Side Determination**

1. The upper end is hook-like, with its concavity directed forwards.
2. The lateral border of the shaft is sharp and crest-like.
3. Pointed styloid process lies medial to the rounded head of ulna.

**ATTACHMENTS ON THE ULNA**

**Muscles**

1. The *triceps* is inserted into the posterior part of the superior surface of the olecranon. The anterior part of the surface is covered by a bursa (Fig. 2.26).
2. The *brachialis* is inserted into the anterior surface of the coronoid process including the tuber-osity of the ulna (Fig. 2.25).
3. The *supinator* arises from the supinator crest and from the triangular area in front of the crest.
4. The ulnar head of the *flexor digitorum superficialis* arises from a tubercle at the upper end of the medial margin of the coronoid process.
The ulnar head of the pronator teres arises from the medial margin of the coronoid process.

The flexor digitorum profundus arises from: (a) the upper three-fourths of the anterior and medial surfaces of the shaft; (b) the medial surfaces of the coronoid and olecranon processes; and (c) the posterior border of the shaft through an aponeurosis which also gives origin to the flexor carpi ulnaris and the extensor carpi ulnaris (Fig. 2.26).

The pronator quadratus takes origin from the oblique ridge on the lower part of the anterior surface.

The flexor carpi ulnaris (ulnar head) arises from the medial side of the olecranon process and from the posterior border (6 c).

The extensor carpi ulnaris arises from the posterior border.

The anconeus is inserted into the lateral aspect of the olecranon process and the upper one-fourth of the posterior surface (Fig. 2.26).

The lateral part of the posterior surface gives origin from above downwards to the abductor pollicis longus, the extensor pollicis longus, and the extensor indicis.

Other Attachments

The interosseous membrane is attached to the interosseous border.

The oblique cord is attached to the lateral side of the tuberosity.

The capsular ligament of the elbow joint is attached to the margins of the trochlear notch, i.e. to the coronoid and olecranon processes.

The annular ligament of the superior radioulnar joint is attached to the two margins of radial notch of ulna.

The ulnar collateral ligament of the wrist is attached to the styloid process.

The articular disc of the inferior radioulnar joint is attached by its apex to a small rough area just lateral to the styloid process.

Ossification: The shaft and most of the upper end ossify from a primary centre which appears during the 8th week of development.

The superior part of the olecranon ossifies from a secondary centre which appears during the 10th year. It forms a scale-like epiphysis which joins the rest of the bone by 16 years. The lower end ossifies from a secondary centre which appears during the 5th year, and joins with the shaft by 18 years. This is the growing end of the bone (Table 2.1).
CUNICAL ANATOMY

1. The ulna is the stabilising bone of the forearm, with its trochlear notch gripping the lower end of the humerus. On this foundation the radius can pronate and supinate for efficient working of the upper limb.

2. The shaft of the ulna may fracture either alone or along with that of the radius. Cross-union between the radius and ulna must be prevented to preserve pronation and supination of the hand.

3. Dislocation of the elbow is produced by a fall on the outstretched hand with the elbow slightly flexed. The olecranon shifts posteriorly and the elbow is fixed in slight flexion. Normally in an extended elbow, the tip of the olecranon lies in a horizontal line with the two epicondyles of the humerus; and in the flexed elbow the three bony points from an equilateral triangle. These relations are disturbed in dislocation of the elbow.

1. Fracture of the olecranon is common and is caused by a fall on the point of the elbow. Fracture of the coronoid process is uncommon, and usually accompanies dislocation of the elbow.

2. Madelung's deformity is dorsal subluxation (displacement) of the lower end of the ulna, due to retarded growth of the lower end of the radius.

Ossification of Humerus, Radius, and Ulna

Law of Ossification

In long bones possessing epiphyses at both of their ends, the epiphysis of that end which appears first is last to join with the shaft. As a corollary, epiphysis which appeared last is first to join.

These ends of long bones which unite last with the shaft are designated as growing end of the bone. In case of long bones of the upper limb, growing ends are at shoulder and wrist joints. This implies that, the upper end of humerus and lower ends of both radius and ulna are growing ends; and each will, therefore, unite with their shaft at a later period than their corresponding ends.

The direction of the nutrient foramen in these bones, as a rule, is opposite to the growing end.

The time of appearance and fusion (either of various parts at one end, or with the shaft) are given in the Table 2.1.

Importance of Capsular Attachments and Epiphyseal Lines

Metaphysis is the epiphyseal end of the diaphysis. It is actively growing part of the bone with rich blood supply. Infections in this part of the bone are most common in the young age. The epiphyseal line is the line of union of metaphysis with the epiphysis. At the end of the bone, besides the epiphyseal line is the attachment of the capsule of the respective joints.

So infection in the joint may affect the metaphysis of the bone if it is partly or completely inside the joint capsule. As a corollary, the disease of the metaphysis if inside a joint may affect the joint. So it is worthwhile to know the intimate relation of the capsular attachment and the epiphyseal line at the ends of humeral, radial and ulnar bones as shown in Table 2.2.

The carpus is made up of 8 carpal bones, which are arranged in two rows (Fig. 2.29).

1. The proximal row contains (from lateral to medial side): (i) the scaphoid, (ii) the lunate, (iii) the triquetral, and (iv) the pisiform bones.

2. The distal row contains in the same order: (i) the trapezium, (ii) the trapezoid, (iii) the capitate, and (iv) the hamate bones.

Identification

1. The scaphoid, is boat-shaped and has a tubercle on its lateral side.

2. The lunate is half-moon-shaped or crescentic.

3. The triquetral is pyramidal in shape and has an isolated oval facet on the distal part of the palmar surface.

4. The pisiform is pea-shaped and has only one oval facet on the proximal part of its dorsal surface.

5. The trapezium is quadrangular in shape, and has a crest and a groove anteriorly. It has a concavoconvex articular surface distally.

6. The trapezoid resembles the shoe of a baby.

7. The capitate is the largest carpal bone, with a rounded head.

8. The hamate is wedge-shaped with a hook near its base.

Side Determination

General Points

1. The proximal row is convex proximally, and concave distally.

2. The distal row is convex proximally and flat distally.

3. Each bone has 6 surfaces.

(i) The palmar and dorsal surfaces are non-articular, except for the triquetral and pisiform.

(ii) (iii) The lateral surfaces of the two lateral bones (scaphoid and trapezium) are non-articular. The medial surfaces of the three medial bones (triquetral, pisiform and hamate) are non-articular.

4. The dorsal non-articular surface is always larger than the palmar non-articular surface, except for the lunate, in which the palmar surface is larger than the dorsal.

The general points help in identifying the proximal, distal, palmar and dorsal surfaces in most of the bones. The side can be finally determined with the help of the specific points.

Specific Points

1. The scaphoid. The tubercle is directed laterally, forward and downwards.

2. The lunate, (i) A small semilunar articular surface for the scaphoid is on the lateral side, (ii) A quadrilateral articular surface for the triquetral is on the medial side.

1. The triquetral. (i) The oval facet for the pisiform lies on the distal part of the palmar surface, (ii) The medial and dorsal surfaces are continuous and non-articular.

2. The pisiform, (i) The oval facet for the triquetral lies on the proximal part of the dorsal surface, (ii) The lateral surface is grooved by the ulnar nerve.

3. The trapezium, (i) The palmar surface has a vertical groove for the tendon of the flexor carpi radialis. (ii) The groove is limited laterally by the crest of the trapezium, (iii) The distal surface bears a concavoconvex articular surface for the base of the first metacarpal bone.

1. The *trapezoid*. (i) The distal articular surface is bigger than the proximal, (ii) The palmar non-articular surface is prolonged laterally.
2. The *capitate*. The dorsomedial angle is the distal-most projection from the body of the capitate. It bears a small facet for the 4th metacarpal bone.
3. The *hamate*. The hook projects from the distal part of the palmar surface, and is directed laterally.

There are four bony pillars at the four corners of the carpus. All attachments are to these four pillars (Fig. 2.30).
1. The tubercle of the scaphoid gives attachment to: (i) the flexor retinaculum; and (ii) a few fibres of the abductor pollicis brevis.

2. The pisiform gives attachment to: (i) flexor carpi ulnaris, (ii) flexor retinaculum, (iii) abductor digiti minimi, and (iv) extensor retinaculum.

3. The trapezium has the following attachments: (i) The crest gives origin to the abductor pollicis brevis, flexor pollicis brevis, and opponens pollicis. These constitute muscles of thenar eminence. Figure 2.31 shows the distribution of median and superficial branch of ulnar nerves in the palm, (ii) The edges of the groove give attachment to the two layers of the flexor retinaculum. (iii) The lateral surface gives
attachment to the lateral ligament of the wrist joint,
(iv) The groove lodges the tendon of the flexor carpi radialis.

4. Hamate, (i) The tip of the hook gives attachment to the flexor retinaculum, (ii) the medial side of the hook gives attachment to the flexor digiti minimi and the opponens digiti minimi (Fig. 2.32).

Articulations

1. The scaphoid articulates with the following bones: radius, lunate, capitate, trapezium and trapezoid.
2. The lunate articulates with the following bones: radius, scaphoid, capitate, hamate and triquetral.
3. The triquetral articulates with the following bones: pisiform, lunate, hamate and articular disc of the inferior radioulnar joint.
4. The pisiform articulates with the triquetral.
5. The trapezium articulates with the following bones: scaphoid, first and second metacarpal and capitate.

</table>

**Fig. 2.34:** Arrangement of carpal bones in man. Compare with Fig. 2.33.

**Ossification:** The year of appearance of centre of ossification in the carpal bones is shown in Figure 2.35A.

1. The metacarpal bones are 5 miniature long bones, which are numbered from lateral to the medial side [Fig. 2.29].
2. Each bone has a head placed distally, a shaft
and a base at the proximal end.

(i) The head is round. It has an articular surface which extends more anteriorly than laterally. It extends more on the palmar surface than on the dorsal surface. The heads of the metacarpal bones form the knuckles.
The base has an elongated articular strip on its lateral side for the fourth metacarpal. The medial side of the base is non-articular and bears a tubercle.

Side Determination

The proximal, distal, palmar and dorsal aspects of each metacarpal bone can be made out from what has been stated above. The lateral and medial sides can be confirmed by the following criteria.

Metacarpal

I. The anterolateral surface is larger than the anteromedial.

II. (i) The medial edge of the groove on the base is deeper than the lateral edge, (ii) The medial side of the base bears an articular strip which is constricted in the middle.

III. (i) The styloid process is dorsolateral, (ii) The lateral side of the base bears an articular strip which is constricted in the middle, (iii) The medial side of the base has two small oval facets for the fourth metacarpal.

IV. (i) The lateral side of the base has two small oval facets for the third metacarpal, (ii) The medial side of the base has an elongated articular strip for the III. fifth metacarpal.

V. (i) The lateral side of the base has an elongated articular strip for the fourth metacarpal, (ii) The medial side of the base is non-articular and has a tubercle.

Main Attachments

The main attachment from shaft of metacarpals is of palmar and dorsal interosseus muscles. Palmar interosseus arise from one bone each except the third metacarpal (Fig. 2.36). Dorsal interosseus arise from adjacent sides of two metacarpals (Fig. 2.37). The other attachments are listed below.

Metacarpal

(i) The opponens pollicis is inserted on the radial border and the anterolateral surface of the shaft (Fig. 2.38).

(ii) The abductor pollicis longus is inserted on the lateral side of the base. (iii) The first palmar in terosseous muscle arises from the ulnar side of the base.

(i) The flexor carpi radialis is inserted on a tubercle on the palmar surface of the base.

(ii) The extensor carpi radialis longus is inserted on the dorsal surface of the base.

(iii) The oblique head of the adductor pollicis arises from the palmar surface of the base (Fig. 2.39). (i) A slip from the flexor carpi radialis is in-

serted on the palmar surface of the base.
(ii) The extensor carpi radialis brev's is inserted on the dorsal surface of the base, immediately beyond the styloid process.

(iii) The oblique head of the adductor pollicis arises from the palmar surface of the base.

(iv) The transverse head of the adductor pollicis arises from the distal two-thirds of the palmar surface of the shaft.

IV. Only the interossei arise from it.

V. (i) The extensor carpi ulnaris is inserted on the tubercle at the base.

(ii) The opponens digit minimi is inserted on the medial surface of the shaft.

**Articulations at the Bases**

IE. With the capitate and the 2nd and 4th metacarpals.

IV. With the capitate, the hamate and the 3rd and 5th metacarpals.

With the hamate and the 4th metacarpal.

Ossification: The shafts ossify from one primary centre each, which appears during the 9th week of development. A secondary centre for the head appears in the 2nd to 5th metacarpals, and for the base in the first metacarpal. It appears during the 2nd-3rd year and fuses with the shaft at about 16-18 years (Fig. 2.35B).

CLINICAL ANATOMY

1. Fracture of the base of the first metacarpal is called Bennett’s fracture. It involves the anterior part of the base, and is caused by a force along its long axis. The thumb is forced into a semiflexed position and cannot be opposed. The fist cannot be clenched.

2. The other metacarpals may also be fractured by direct or indirect violence. Direct violence usually displaces the fractured segment forwards. Indirect violence displaces them backwards.

3. Tubercular or syphilitic disease of the metacarpals or phalanges is located in the middle of the diaphysis rather than in the metaphysis because the nutrient artery breaks up into a plexus immediately upon reaching the medullary cavity. In adults, however, the chances of infection are minimized because the nutrient artery is replaced (as the major source of supply) by periosteal vessels.

4. When the thumb possesses three phalanges, the first metacarpal has two epiphyses one at each end. Occasionally, the first metacarpal bifurcates distally. Then the medial branch has no distal epiphysis, and has only two phalanges. The lateral branch has a distal epiphysis and three phalanges.

ATTACHMENTS

7. Base of the Distal Phalanx

(i) The flexor digitorum profundus is inserted on the palmar surface (Fig. 2.40). (ii) Two side slips of digital expansion fuse to be inserted on the dorsal surface. These also extend the insertion of lumbrical and interossei muscles (Fig. 2.41).

2. The Middle Phalanx

(i) The flexor digitorum superficialis is inserted on each side of the shaft, (ii) The fibrous flexor sheath is also attached to the side of the shaft, (iii) A part of the extensor digitorum is inserted on the dorsal surface of the base (Fig. 2.41).

3. The Proximal Phalanx

(i) The fibrous flexor sheath is attached to the sides of the shaft, (ii) On each side of the base, parts of the lumbricals and interossei are inserted.

4. In the thumb, the base of the proximal phalanx provides attachments to the following structures (Fig. 2.36).

(i) The abductor pollicis brevis and flexor pollicis brew’s are inserted on the lateral side.

(ii) The adductor pollicis and the first palmar interosseous are inserted on the medial side.

(iii) The extensor pollicis brevis is inserted on the dorsal surface.

5. In the little finger, the medial side of the base of the proximal phalanx provides insertion to the abductor digit minimi and the flexor digitii minimi.
Fig. 2.40: The fibrous flexor sheath and its contents. (A) Bony attachments of the sheath and of the flexor tendons. (B) The fibrous sheath showing transverse fibres in front of the bones and cruciate fibres in front of joints. (C) The flexor tendons after removal of the sheath.
The secondary centre appears for the base during 2-4 years and fuses with the shaft during 15-11 years (Fig. 2.35).

Ossification: The shaft of each phalanx ossifies from a primary centre which appears during the 8th week of development in the distal phalanx, 10th week in the proximal phalanx and 12th week in the middle phalanx.

THE SESAMOID BONES OF THE UPPER LIMB

Sesamoid bones are small rounded masses of bone located in some tendons at points where they are subjected to great pressure. They are variable in their occurrence. These are as follows.

1. The pisiform is often regarded as a sesamoid bone lying within the tendon of the flexor carpi ulnaris.
2. Two sesamoid bones are always found on the palmar surface of the head of the first metacarpal bone.
3. One sesamoid bone is found in the capsule of the interphalangeal joint of the thumb, in 75% of subjects.
4. One sesamoid bone is found on the ulnar side of the capsule of the metacarpo phalangeal joint of the little finger, in about 75% of subjects.
5. Less frequently, there is a sesamoid bone on the lateral side of the metacarpophalangeal joint of the index finger.
6. Sometimes sesamoid bone may be found at other metacarpophalangeal joints.

The Metacarpal Bones

The Pectoral Region

The pectoral region lies on the front of the chest. It essentially consists of structures which connect the upper limb to the anterolateral chest wall.

SURFACE LANDMARKS

The following features of the pectoral region can be seen or felt on the surface of body.

1. The clavicle lies horizontally at the root of the neck, separating it from the front of the chest. The bone is subcutaneous, and therefore palpable, throughout its length. It is convex forwards in its medial two-thirds, and concave forwards in its lateral one-third. Medially, it articulates with the sternum at the sternoclavicular joint, and laterally with the acromion at the acromioclavicular joint. Both the joints are palpable because of the upward projecting ends of the clavicle (Fig. 3.1). The sternoclavicular joint may be masked by the sternocleidomastoid muscle.

2. The jugular notch (interclavicular or suprasternal notch) lies between the medial ends of the clavicles, at the superior border of the manubrium sterni.

3. The sternal angle (angle of Louis) is felt as a transverse ridge about 5 cm below the jugular notch (Fig. 3.1). It marks the manubriosternal joint. Laterally, on either side, the second costal cartilage joins the sternum at this level. The sternal angle thus serves as a landmark for identification of the second rib. Other ribs can be identified by counting downwards from the second rib.

4. The epigastric fossa (pit of the stomach) is the depression in the infrasternal angle. The fossa overlies the xiphoid process, and is bounded on each side by the seventh costal cartilage.

5. The nipple is markedly variable in position in females. In males, and in immature females, it usually lies in the fourth intercostal space just medial to the midclavicular line; or 10 cm from the midsternal line. In fact, the position of the nipple is variable even in males.

1. The midclavicular line passes vertically through the tip of the ninth costal cartilage and the midinguinal point.

2. The infraclavicular fossa (deltopectoral triangle) is a triangular depression below the junction of the lateral and middle thirds of the clavicle. It is bounded medially by the pectoralis major, laterally by the anterior fibres of the deltoid, and superiorly by the clavicle.
1. The tip of the coracoid process of the scapula lies 2-3 cm below the clavicle, overlapped by the anterior fibres of the deltoid. It can be felt on deep palpation just lateral to the infraclavicular fossa.

2. The acromion of the scapula (acron = summit; omos = shoulder) is a flattened piece of bone that lies, subcutaneously forming the top of the shoulder. The posterior end of its lateral border is called the acromial angle, where it is continuous with the lower lip of the crest of the spine of the scapula. The anterior end of its medial border articulates with the clavicle at the acromioclavicular joint. The joint can be felt because the clavicle projects slightly above the acromion.

1. The deltoid is triangular muscle with its apex directed downwards. It forms the rounded contour of the shoulder, extending vertically from the acromion to the deltoid tuberosity of the humerus.

2. The axilla (or armpit) is a pyramidal space between the arm and chest. When the arm is raised (abducted) the floor of the axilla rises, the anterior and posterior folds stand out, and the space becomes more prominent. The anterior axillary fold contains the lower border of the pectoralis major, and posterior axillary fold contains the tendon of the latissimus dorsi winding round the fleshy teres major.

The medial wall of the axilla is formed by the upper 4 ribs covered by the serratus anterior. The narrow lateral wall presents the upper part of the humerus covered by the short head of the biceps, and the coracobrachialis. Axillary arterial pulsations can be felt by pressing the artery against the humerus. The cords of the brachial plexus can also be rolled against the humerus. The head of the humerus can be felt by pressing the fingers upwards into the axilla.

12. The midaxillary line is a vertical line drawn midway between the anterior and posterior axillary folds.

**SUPERFICIAL FASCIA**

The superficial fascia of the pectoral region is visualised after the skin has been incised. It contains moderate amount of fat, and is continuous with that of surrounding regions. The mammary gland, which is well developed in females, is the most important of all contents of this fascia. The fibrous septa given off by the fascia support the lobes of the gland, and the skin covering the gland.

**Contents**

In addition to fat, the superficial fascia of the pectoral region contains: (i) cutaneous nerves derived from the cervical plexus and from the intercostal nerves; (ii) cutaneous branches from the internal thoracic and posterior intercostal arteries; (iii) the platysma; and (iv) the breast.

**DISSECTION**

Mark the following points: (i) centre of the suprasternal notch; (ii) xiphoid process, (iii) 7 o'clock position at the margin of areola, and (iv) lateral end of clavicle (Fig. 3.2).

Give an incision vertically down from the first point to the second which joins the centre of the suprasternal notch to the xiphoid process in the midsagittal plane. From the lower end of this line, extend the incision upward and laterally till you reach to the third point on the areolar margin. Encircle the areola and carry the incision upwards and laterally till the anterior axillary fold is reached. Continue the line of incision downwards along the medial border of the upper arm till its junction of upper one-third and lower two-thirds. Extend this incision transversely across the arm. Make another incision horizontally from the xiphoid process across the chest wall till the posterior axillary fold. Lastly give horizontal incision from the centre of suprasternal notch to the lateral (acromial) end of the clavicle.

![Fig. 3.2: Points and lines of Incision.](image-url)
Cutaneous Nerves of the Pectoral Region

The cutaneous nerves of the pectoral region are as follows (Figs 3.3, 3.4):

1. The *medial, intermediate and lateral supraclavicular nerves are* branches of the cervical plexus (C3, C4). They supply the skin over the upper half of the deltoid and from the clavicle down to the second rib.

2. The *anterior and lateral cutaneous branches* of the second to sixth intercostal nerves supply the skin below the level of the second rib. The intercostobrachial nerve T2 supplies the skin of the floor of the axilla and the upper half of the medial side of the arm (Fig. 3.3).

It is of interest to note that the area supplied by spinal nerves C3 and C4 directly meets the area supplied by spinal nerves T2 and T3. This is because of the fact that the intervening nerves (C5, C6, C7, C8, T1) have been ‘pulled away’ to supply the upper limb. It may also be noted that normally the areas supplied by adjoining spinal nerves overlap, but because of what has been said above there is hardly any overlap between the areas supplied by C3 and C4 above and T2 and T3 below (Fig. 3.4).

Cutaneous Vessels

The cutaneous vessels are very small. The anterior cutaneous nerves are accompanied by the *perforating branches of the internal thoracic artery*. The second, third and fourth of these branches are large in females for supplying the breast. The lateral cutaneous nerves are accompanied by the *lateral cutaneous branches of the posterior intercostal arteries*.

Platysma

The platysma is a thin, broad sheet of subcutaneous muscle. The fibres of the muscle arise from the deep fascia covering the pectoralis major; run upwards and medially crossing the clavicle and the side of the neck; and are inserted into the base of the mandible, and into skin over the posterior and lower part of the face. The platysma is supplied by the *facial nerve*. When the angle of the mouth is pulled down, the muscle contracts and wrinkles the skin of the neck. The platysma may protect the external jugular vein (which underlies the muscle) from external pressure.

THE BREAST/MAMMARY GLAND

The breast, or mammary gland, is the most important structure present in the pectoral region. Its anatomy is of great practical importance and has to be studied in detail.

The breast is found in both sexes, but is rudimentary in the male. It is well developed in the female after puberty. The breast is a modified sweat gland. It forms an important accessory organ of the female reproductive system, and provides nutrition to the newborn in the form of milk.

Situation

The breast lies in the superficial fascia of the pectoral region. A small extension called the axillary tail of Spence, pierces the deep fascia and lies in the axilla (Figs 3.5, 3.6).
Extent

(i) Vertically, it extends from the second to the sixth rib.
(ii) Horizontally, it extends from the lateral border of the sternum to the mid-axillary line.

Deep Relations

The deep surface of the breast is related to the following structures in that order (Figs 3.7, 3.8).

1. The breast lies on the deep fascia (pectoral fascia) covering the pectoralis major.
2. Still deeper there are the parts of three muscles, namely the pectoralis major, the serratus anterior, and the external oblique muscle of the abdomen.
3. The breast is separated from the pectoral fascia by loose areolar tissue, sometimes called the retromammary space. Because of the presence of this loose tissue the normal breast can be moved freely over the pectoralis major.
Structure of the Breast

The structure of the breast may be conveniently studied by dividing it into the skin, the parenchyma, and the stroma.

A. The skin:  It covers the gland and presents the following features.

1. A conical projection called the nipple is present just below the centre of the breast at the level of the fourth intercostal space. The nipple is pierced by 15 to 20 lactiferous ducts. It contains circular and longitudinal smooth muscle fibres which can make the nipple stiff or flatten it, respectively. It has a few modified sweat and sebaceous glands. It is rich in its nerve supply and has many sensory end organs at the terminations of nerve fibres.

2. The skin surrounding the base of the nipple is pigmented and forms a circular area called the areola. This region is rich in modified sebaceous glands, particularly at its outer margin. These become enlarged during pregnancy and lactation to
form raised tubercles of Montgomery. Oily secretions of these glands lubricate the nipple and areola, and prevent them from cracking during lactation. Apart from sebaceous glands the areola also contains some sweat glands and accessory mammary glands. The skin of the areola and nipple is devoid of hair, and there is no fat subjacent to it.

**B. The parenchyma:** It is made up of glandular tissue which secretes milk. The gland consists of 15 to 20 lobes. Each lobe is a cluster of alveoli, and is drained by a lactiferous duct. The lactiferous ducts converge towards the nipple and open on it. Near its termination each duct has a dilatation called a lactiferous sinus (Figs 3.9, 3.10).

*Alveolar epithelium* is cuboidal in the resting phase, and columnar during lactation. In distended alveoli, the cells may appear cuboidal due to stretching, but they are much larger than those in the resting phase. The *smaller ducts* are lined by columnar epithelium, the *larger ducts* by two or more layers of cells, and the terminal parts of the lactiferous ducts by stratified squamous keratinized epithelium. The passage of the milk from the alveoli into and along the ducts is facilitated by contraction of *myoepitheliocytes*, which are found both around the alveoli and around the ducts, lying between the epithelium and the basement membrane.

**C. The stroma:** It forms the supporting framework of the gland. It is partly fibrous and partly fatty.

The fibrous stroma forms septa, known as the suspensory ligaments (of Cooper) which anchor the skin and gland to the pectoral fascia (Fig. 3.11).

The fatty stroma forms the main bulk of the gland. It is distributed all over the breast, except beneath the areola and nipple.

**Blood Supply**

The mammary gland is extremely vascular. It is supplied by branches of the following arteries (Fig. 3.12).
1. Internal thoracic artery, a branch of the subclavian artery, through its perforating branches.
2. The lateral thoracic, superior thoracic and acromiothoracic (thoracoacromial) branches of the axillary artery.
3. Lateral branches of the posterior intercostal arteries.

The arteries converge on the breast and are distributed from the anterior surface. The posterior surface is relatively avascular.

The veins follow the arteries. They first converge towards the base of the nipple where they form an anastomotic venous circle, from where veins run in superficial and deep sets.

1. The superficial veins drain into the internal thoracic vein and into the superficial veins of the lower part of the neck.
2. The deep veins drain into the internal thoracic, axillary and posterior intercostal veins.

**Nerve Supply**

The breast is supplied by the anterior and lateral cutaneous branches of the 4th to 6th intercostal nerves. The nerves convey sensory fibres to the skin, and autonomic fibres to smooth muscle and to blood vessels. The nerves do not control the secretion of milk. Secretion is controlled by the hormone prolactin, secreted by the pars anterior of the hypophysis cerebri.

**Lymphatic Drainage**

Lymphatic drainage of the breast assumes great importance to the surgeon because, carcinoma of
the breast spreads mostly along lymphatics to the regional lymph nodes. The subject can be described under two heads, the lymph nodes, and the lymphatics.

**Lymph Nodes**

Lymph from the breast drains into the following lymph nodes (Fig. 3.13).

1. The axillary lymph nodes, chiefly the anterior (or pectoral) group. The posterior, lateral, central and apical groups of nodes also receive lymph from the breast either directly or indirectly.
2. The internal mammary (parasternal) nodes which lie along the internal thoracic vessels.
3. Some lymph from the breast also reaches the supraclavicular nodes, the cephalic (deltoidpectoral) node, the posterior intercostal nodes (lying in front of the heads of the ribs), the subdiaphragmatic and subperitoneal lymph plexuses.

**Lymphatic Vessels**

A. The superficial lymphatics drain the skin over the breast except for the nipple and areola. The lymphatics pass radially to the surrounding lymph nodes (axillary, internal mammary, supraclavicular and cephalic).

B. The deep lymphatics drain the parenchyma of the breast. They also drain the nipple and areola (Fig. 3.14).

Some further points of interest about the lymphatic drainage are as follows.

1. About 75% of the lymph from the breast drains into the axillary nodes; 20% into the internal mammary nodes; and 5% into the posterior intercostal nodes. Among the axillary nodes, the lymphatics end mostly in the anterior group (closely related to the axillary tail) and partly in the posterior and apical groups. Lymph from the anterior and posterior groups passes to the central and lateral groups, and through them to the apical group. Finally it reaches the supraclavicular nodes.

2. A plexus of lymph vessels is present deep to the areola. This is the subareolar plexus (of Sappy) (Fig. 3.15).
Subareolar plexus and most of lymph from the breast drains into the anterior or pectoral group of lymph nodes.

3. The lymphatics from the deep surface of the breast pass through the pectoralis major muscle and the clavipectoral fascia to reach the apical nodes, and also to the internal mammary nodes (Fig. 3.16).

4. Lymphatics from the lower and inner quadrants of the breast may communicate with the subdiaphragmatic and subperitoneal lymph plexuses after crossing the costal margin and then piercing the anterior abdominal wall through the upper part of the linea alba.
Fig. 3.16: Deep lymphatics of the breast passing to the apical lymph nodes.

divide and subdivide to form the lobes of the gland. The entire system is first solid, but is later canalized. At birth or later, the nipple is everted at the site of the original pit.

1. Growth of the mammary glands, at puberty, is caused by oestrogens. Apart from oestrogens, development of secretory alveoli is stimulated by progesterone and by the prolactin hormone of the hypophysis cerebri.

2. Developmental anomalies of the breast are: (a) amastia (absence of the breast); (b) athelia (absence of nipple); (c) polymastia (supernumerary breasts); (d) polythelia (supernumerary nipples); (e) gynae-comastia (development of breasts in a male). Gynae-comastia occurs in Klinefelter's syndrome.

Human Milk

Human milk is composed of about 88% water, 7% lactose, 4% fat, and 1% protein (caseins and lactal-
bumin). It also contains various ions (calcium, phosphate, sodium, potassium and chloride), vitamins and antibodies of IgA variety.

Milk secreted in the later part of pregnancy, and for a few days after parturition is known as colostrum. It is rich in fat and poor in nutrients, the fat being contained in colostral corpuscles. It is rich in immunoglobulins.

Under the influence of maternal oestrogens, the infant's breast may secrete milk during the first one or two weeks after birth, a fat-free fluid called 'witch's milk'.

Lactation in mothers is active for about 5-6 months after parturition and then diminishes progressively, so that the infant is weaned by about 9 months of age.

**CLINICAL ANATOMY**

The breast is a frequent site of carcinoma (cancer). Several anatomical facts are of importance in diagnosis and treatment of this condition. Abscesses may also form in the breast and may require drainage. The following facts are worthy of note.

1. Incisions into the breast are usually made radially to avoid cutting the lactiferous ducts.
2. Cancer cells may infiltrate the suspensory ligaments. The breast then becomes fixed. Contraction of the ligaments can cause retraction or puckering (folding) of the skin.
3. Infiltration of lactiferous ducts and their consequent fibrosis can cause retraction of the nipple.
4. Obstruction of superficial lymph vessels by cancer cells may produce oedema of the skin giving rise to an appearance like that of the skin of an orange (peau d'orange appearance).
5. Because of communications of the superficial lymphatics of the breast across the midline, cancer may spread from one breast to the other.
6. Because of communications of the lymph vessels with those in the abdomen, cancer of the breast may spread to the liver, and cancer cells may 'drop' into the pelvis producing secondaries there.
7. Apart from the lymphatics cancer may spread through the veins. In this connection, it is important to know that the veins draining the breast communicate with the vertebral venous plexus of veins. Through these communications cancer can spread to the vertebrae and to the brain.
DEEP PECTORAL FASCIA

The deep fascia covering the pectoralis major muscle is called the pectoral fascia. It is thin and closely attached to the muscle by numerous septa passing between the fasciculi of the muscle. It is attached superiorly to the clavicle, and anteriorly to the sternum. Superolaterally, it passes over the infraclavicular fossa and deltopectoral groove to become continuous with the fascia covering the deltoid. Inferolaterally, the fascia curves round the inferolateral border of the pectoralis major to become continuous with the axillary fascia. Inferiorly, it is continuous with the fascia over the thorax and the rectus sheath.

The pectoral fascia is connected with the clavipectoral fascia by a septum passing deep along the deltopectoral groove. The cephalic vein, the deltoid branch of the thoraco-acromial artery, and one or two deltopectoral lymph nodes lie in the deltopectoral groove, under the deep fascia on the medial side of the septum.

MUSCLES OF THE PECTORAL REGION

Muscles of the pectoral region are described in Tables 3.1 and 3.2. Some additional features are given below.

A. Pectoralis Major

7. Structures under Cover of Pectoralis Major

(a) Bones and cartilages: sternum, ribs, and costal cartilages.
(b) Fascia: clavipectoral.
(c) Muscles: subclavius, pectoralis minor, serratus anterior, intercostal, and upper parts of the biceps and coracobrachialis.
(d) Vessels: axillary.
(e) Nerves: cords of brachial plexus with their branches.

2. Bilaminar Tendon of Pectoralis Major

The muscle is inserted by a bilaminar tendon into the lateral lip of the intertubercular sulcus of the humerus.

The anterior lamina is thicker and shorter than the posterior. It receives two strata of muscle fibres: superficial fibres arising from the clavicle and deep fibres arising from the manubrium (Fig. 3.18).

The posterior lamina is thinner and longer than the anterior lamina. It is formed by fibres from the front of the sternum, 2nd to 6th ribs and their costal cartilages and from the aponeurosis of the external oblique muscle of the abdomen. Out of these only the
<table>

</tr>
</thead>
</table>
| Pectoralis major (Fig. 3.18) | (i) Anterior surface of medial half of clavicle  
(ii) Half the breadth of anterior surface of manubrium and sternum up to 6th costal cartilages  
(iii) Second to sixth costal cartilages (iv) Aponeurosis of the external oblique muscle of abdomen | It is inserted by a bilaminar tendon on the lateral lip of the bicipital groove  
The two laminae are continuous with each other interiorly | Medial and lateral pectoral nerves |
| Pectoralis minor (Fig. 3.19) | (i) 3, 4, 5 ribs, near the costochondral junction  
(ii) Intervening fascia covering external intercostal muscles | Medial border and upper surface of the coracoid process | Medial and lateral pectoral nerves |
| Subclavius (Fig. 3.20) | First rib at the costochondral junction | Subclavian groove in the middle one-third of the clavicle | Nerve to subclavius from upper trunk of brachial plexus |
fibres from the sternum and aponeurosis are twisted around the lower border of the rest of the muscle. The twisted fibres form the anterior axillary fold. These fibres pass upwards and laterally to get inserted successively higher into the posterior lamina of the tendon. Fibres arising lowest, find an opportunity to get inserted the highest and form a crescentic fold which fuses with the capsule of the shoulder joint.

Fig. 3.18: (A) The origin and Insertion of the pectoralis major muscle. (B) The bilaminar insertion of the pectoralis major. The anterior lamina is formed by the clavicular and manubrial fibres; the rest of the sternocostal and abdominal fibres form the posterior lamina. Part of the posterior lamina is twisted upside down.

3. Variation
Superficial to the pectoralis major, some muscle fibres may pass vertically from the lower costal cartilages and rectus sheath to blend above with the sternocleidomastoid, or to be attached to the upper sternum or costal cartilages. These fibres constitute the sternalis muscle or the rectus sternalis.

4. Clinical Testing
(i) The clavicular head of the pectoralis major can be tested by attempting to lift a heavy table/rod. The sternocostal head can be tested by trying to depress a heavy table/rod.

(ii) The clavicular head can also be tested by flexing the arm to a right angle; the sternocostal head by extending the flexed arm against resistance.

(iii) Press the fists against each other (Fig. 3.21).

B. Pectoralis Minor

1. The costal origin of the pectoralis minor is variable. Most commonly it arises from the 3rd to 5th ribs near their costochondral junctions (Fig. 3.19). The origin may be prefixed (from 2nd to 4th ribs) or postfixed (from 4th to 6th ribs).

2. The tendon of insertion of the pectoralis minor may cross the coracoid process to blend with the coracoacromial ligament, or may pass through this ligament to blend with the coracohumeral ligament, thus reaching the humerus.

3. Variation: Rarely, some separated fibres of the pectoralis minor pass from the first rib to the coracoid process. These fibres constitute the pectoralis minimus muscle.

DISSECTION

Identify the extensive pectoralis major muscle in the pectoral region and the prominent deltoid muscle on the lateral aspect of the shoulder joint and upper arm. Demarcate the deltopectoral groove by removing the deep fascia. Now identify the cephalic vein, a small artery and few lymph nodes in the groove.

Clean the fascia over the pectoralis major muscle and look for its attachments. Divide the clavicular head of the muscle and reflect it laterally. Medial and lateral pectoral nerves will be seen supplying the muscle. Make a vertical incision 5 to 6 cm from the lateral border of sternum and reflect its sternocostal head laterally. Identify the pectoralis minor muscle under the central part of the pectoralis major. Note clavipectoral fascia extending between pectoralis minor muscle and the clavicle bone. Identify the structures piercing the clavipectoral fascia: these are cephalic vein, acromiothoracic artery, and lateral pectoral nerve. If some fine vessels are also seen, these are the lymphatic channels. Also, identify the serratus anterior muscle showing serrated digitations on the side of the chest wall.

Clavipectoral Fascia

Clavipectoral fascia is a fibrous sheet situated deep to the clavicular portion of the pectoralis major muscle. It extends from the clavicle above to the axillary fascia below (Fig. 4.2). Its upper part splits to enclose the subclavius muscle (Fig. 3.20). The posterior lamina is fused to the investing layer of the deep cervical fascia and to the axillary sheath. Inferiorly, the clavipectoral fascia splits to enclose the pectoralis minor muscle. Below this muscle it continues as the suspensory ligament which is attached to the dome of the axillary fascia, and helps to keep it pulled up.
Medially the fascia is attached to the first rib and to the costoclavicular ligament. Laterally, it is attached to the coracoid process and blends with the coracoclavicular ligament.

The upper part of the fascia is thick and is called the costocoracoid ligament.

The clavipectoral fascia is pierced by the following structures: (i) Lateral pectoral nerve; (ii) cephalic vein; (iii) thoracoacromial vessels; and (iv) lymphatics passing from the breast and pectoral region to the apical group of axillary lymph nodes.

**Serratus Anterior**

Serratus anterior muscle is not strictly a muscle of the pectoral region, but it is convenient to consider it here.

**Origin**

Serratus anterior muscle arises by eight digitations from the upper eight ribs, and from the fascia covering the intervening intercostal muscles (Figs 3.22, 3.23).

**Insertion**

The muscle is inserted into the costal surface of the scapula along its medial border. The first digitation is inserted from the superior angle to the root of the spine. The next two or three digitations are inserted lower down on the medial border. The lower four or five digitations are inserted into a large triangular area over the inferior angle.

**Actions**

1. Along with the pectoralis minor, the muscle pulls the scapula forwards around the chest wall to protract the upper limb (in pushing and punching movements).
2. The fibres inserted into the inferior angle of the scapula pull it forwards and rotate the scapula so that the glenoid cavity is turned upwards. In this action, the serratus anterior is helped by the trapezius which pulls the acromion upwards and backwards.

When the muscle is paralysed the medial margin of the scapula gets raised especially when 'pushing movements' are attempted. This is called 'winging of the scapula'.

1. The muscle steadies the scapula during weight carrying.
2. It helps in forced inspiration.

**Additional Features**

1. Paralysis of the serratus anterior produces 'winging of scapula' in which the inferior angle and the medial border of the scapula are unduly prominent. The patient is unable to do any pushing action, nor can he raise his arm above the head. Any attempt to do these movements makes the inferior angle of the scapula still more prominent.
2. Clinical testing: Forward pressure with the hands against a wall, or against resistance offered by the examiner makes the inferior angle of the scapula prominent (winging of scapula) if the serratus anterior is paralysed (Fig. 4.10).
3. Electromyography has disproved the popular view that the serratus anterior is an accessory muscle of respiration.

References and Additional Reading

The axilla or armpit is a pyramidal space situated between the upper part of the arm and the chest wall. It resembles a four-sided pyramid, and has (i) an apex, (ii) a base, and (iii) 4 walls—anterior, posterior, medial and lateral.

The axilla is disposed obliquely in such a way that the apex is directed upwards and medially towards the root of the neck, and the base is directed downwards.

**BOUNDARIES**

1. **Apex:** It is directed upwards and medially towards the root of the neck.
   
   It is truncated (not pointed), and corresponds to a triangular interval bounded anteriorly by the clavicle, posteriorly by the superior border of the scapula, and medially by the outer border of the first rib. This passage is called the cervicoaxillary canal (Fig. 4.1). The axillary artery and the brachial plexus enter the axilla through this canal.
2. **Base or floor:** It is directed downwards, and is formed by skin and fasciae.

3. **Anterior wall:** It is formed by the following:
   (i) The pectoralis major in front (Fig. 4.2), and
   (ii) The clavipectoral fascia enclosing the pectoralis minor and the subclavius; all deep to the pectoralis major.

4. **Posterior wall:** It is formed by:
   (i) Subscapularis above (Fig. 4.3).
   (ii) Teres major and latissimus dorsi below.

5. **Medial wall:** It is formed by:
   (i) Upper four ribs with their intercostal muscles, (ii) Upper part of the serratus anterior muscle.

6. **Lateral wall:** It is very narrow because the anterior and posterior walls converge on it. It is formed by:
   (i) Upper part of the shaft of the humerus in the region of the bicipital groove, and (ii) Coracobrachialis and short head of the biceps.
Dissection

Place a rectangular wooden block under the neck and shoulder region of cadaver (Fig. 4.4). Ensure that the block supports the body firmly. Abduct the limb at right angles to the trunk; and strap the wrist firmly on slab projecting toward your side. Reflect the lower skin flap till the posterior axillary fold made up by the subscapularis, teres major, and latissimus dorsi muscles is seen. Clean the fat, and remove the lymph nodes and superficial veins to reach depth of the armpit. Identify two muscles arising from the tip of the coracoid process of scapula; Out of these, the short head of biceps brachii muscles lies on the lateral side and the coracobrachialis on the medial side. The pectoral muscles with the clavipectoral fascia form anterior boundary of the region. Look for upper three intercostal muscles and serratus anterior muscle which make the medial wall of axilla. Clean and identify the axillary vessels. Trace the course of the branches of the axillary artery.

Contents of the Axilla

1. Axillary artery and its branches (Fig. 4.5).
2. Axillary vein and its tributaries.
3. Infraclavicular part of the brachial plexus.
4. Five groups of axillary lymph nodes and the associated lymphatics.
5. The long thoracic and intercostobrachial nerves.
6. Axillary fat and areolar tissue in which the other contents are embedded.
Layout

1. Axillary artery and the brachial plexus of nerves I run from the apex to the base along the lateral wall of the axilla, nearer to the anterior wall than the posterior wall.

2. The thoracic branches of the axillary artery lie in contact with the pectoral muscles, the lateral thoracic vessels running along the lower border of the pectoralis minor.

3. The subscapular vessels run along the lower border of the subscapularis. The subscapular nerve and the thoracodorsal nerve (nerve to latissimus dorsi) cross the anterior surface of the muscle. The circumflex scapular vessels wind round the lateral border of the scapula. The axillary nerve and the posterior circumflex humeral vessels pass backwards close to the surgical neck of the humerus.
1. The medial wall of the axilla is avascular, except for a few small branches from the superior thoracic artery. However, the long thoracic nerve (or nerve to the serratus anterior) descends on the surface of the muscle, and the intercostobrachial nerve pierces the anterosuperior part of the medial wall and crosses the spaces to reach the medial side of the arm.

2. The axillary lymph nodes are 20 to 30 in number, and are arranged in five sets. The anterior group lies along the lower border of the pectoralis minor, on the lateral thoracic vessels. The posterior group lies along the lower margin of the posterior wall along the subscapular vessels. The lateral group lies posteromedial to the axillary vein. The central group lies in the fat of the axilla. The apical group lies behind and above the pectoralis minor, medial to the axillary vein.

The plexus consists of roots, trunks, divisions, cords and branches (Figs 4.6, 4.7).

1. **Roots:** These are constituted by the anterior primary rami of spinal nerves C5, 6, 7, 8 and T1, with contributions from the anterior primary rami of C4 and T2 (Fig. 5.2). The origin of the plexus may shift by one segment either upward or downward, resulting in a prefixed or postfixed plexus respectively. In a prefixed plexus, the contribution by C4 is large and that from T2 is often absent. In a postfixed plexus, the contribution by T1 is large, T2 is always present, C4 is absent, and C5 is reduced in size. The roots join to form trunks as follows:

![Fig. 4.6: Diagram of a spinal nerve.](image)

![Fig. 4.7: The brachial plexus.](image)
1. **Trunks:** Roots C5 and C6 join to form the *upper* trunk. Root C7 forms the *middle* trunk. Roots C8 and T1 join to form the *lower* trunk.

2. **Divisions of the trunks:** Each trunk divides into ventral and dorsal divisions (which ultimately supply the anterior and posterior aspects of the limb). These divisions join to form cords.

3. **Cords:**
   - (i) The lateral cord is formed by the union of the ventral divisions of the upper and middle trunks.
   - (ii) The medial cord is formed by the ventral division of the lower trunk.
   - (iii) The posterior cord is formed by union of the dorsal divisions of all the three trunks.

**DISSECTION**

After cleaning the branches of the axillary artery, proceed to clean the brachial plexus. It is made up by the ventral primary rami of the lower four cervical (C5-C8) and the first thoracic (T1) nerves. The first and second parts of the axillary artery are related to the cords; and third part is related to the branches of the plexus. Study the description of the brachial plexus before proceeding further.

**A. Branches of the Roots**

1. Nerve to serratus anterior (long thoracic nerve) I (C5, 6, 7)
2. Nerve to rhomboideus (dorsal scapular nerve) I (C5)

**B. Branches of the Trunks**

These arise only from the upper trunk which gives two branches.

1. Suprascapular nerve (C5, 6)
2. Nerve to subclavius (C5, 6)

**C. Branches of the Cords**

(a) **Branches of Lateral Cord**

1. Lateral pectoral (C5-C7)
2. Musculocutaneous (C5-C7)
3. Lateral root of median (C5-C7)

(b) **Branches of Medial Cord**

1. Medial pectoral (C8, T1)
2. Medial cutaneous nerve of arm (C8, T1)
3. Ulnar (C7, C8, T1). C7 fibres reach by a communicating branch from lateral root of median nerve.
4. Medial root of median (C8, T1)

(c) **Branches of Posterior Cord**

1. Upper subscapular (C5, C6)
2. Nerve to latissimus dorsi (thoracodorsal) (C6, C7, C8)
3. Lower subscapular (C5, C6)
4. Axillary (circumflex) (C5, C6)
5. Radial (C5-C8, T1)

In addition to the branches of the brachial plexus, the upper limb is also supplied, near the trunk, by the supraclavicular branches of the cervical plexus, and by the intercostobrachial branch of the second intercostal nerve. Sympathetic nerves are distributed through the brachial plexus. The arrangement of the various nerves in the axilla will be studied with the relations of the axillary artery.

**CLINICAL ANATOMY**

Injuries to roots, trunks and cords of the brachial plexus may produce characteristic defects, which are described here. Injury to the individual nerves are dealt with each nerve.
Erb's Paralysis

Site of injury: The region of the upper trunk of the brachial plexus is called Erb's point (Fig. 4.8). Six nerves meet here. Injury to the upper trunk causes Erb's paralysis (Fig. 4.9).

Causes of injury. Undue separation of the head from the shoulder, which is commonly encountered in: (i) birth injury, (ii) fall on the shoulder, and (iii) during anaesthesia.

Deformity (position of the limb)
Arm: Hangs by the side; it is adducted and medially rotated.
Forearm: Extended and pronated.
The deformity is known as 'policeman's tip hand' or 'porter's tip hand'.

Disability: The following movements are lost.
1. Abduction and lateral rotation of the arm (shoulder).
2. Flexion and supination of the forearm.
3. Biceps and supinator jerks are lost.
4. Sensations are lost over a small area over the lower part of the deltoid.

Klumpke's Paralysis

Site of injury. Lower trunk of the brachial plexus.

Cause of injury. Undue abduction of the arm, as in clutching something with the hands after a fall from a height, or sometimes in birth injury.

Nerve roots involved. Mainly T1 and partly C8.

Muscles Paralysed

1. Intrinsic muscles of the hand (T1).
2. Ulnar flexors of the wrist and fingers (C8).

Deformity (position of the hand). Claw hand due to the unopposed action of the long flexors and extensors of the fingers. In a claw hand there is hyperextension at the metacarpophalangeal joints and flexion at the interphalangeal joints.

Disability
1. Claw hand.
2. Cutaneous anaesthesia and analgesia in a narrow zone along the ulnar border of the forearm and hand.
3. Horner's syndrome—ptosis, miosis, anhydrosis, enophthalmos, and loss of ciliospinal reflex—may be associated. (This is because of injury to sympathetic fibres to the head and neck that leave the spinal cord through nerve T1.)
1. Vasomotor changes: The skin areas with sensory loss is warmer due to arteriolar dilation. It is also drier due to the absence of sweating as there is loss of sympathetic activity.
2. Trophic changes: Long-standing case of paralysis leads to dry and scaly skin. The nails crack easily with atrophy of the pulp of fingers.

Injury to the Nerve to Serratus Anterior (Nerve of iBell> M < (§)

Causes: 1. SiMden pressure on the shoulder from above. 2. Carrying heavy loads on the shoulder.

Deformity: Winging of the scapula, i.e. excessive prominence of the medial border of the scapula. Normally, the pull of the muscle keeps the medial border against the thoracic wall.

Disability
1. Loss of pushing and punching actions. During attempts at pushing, there occurs winging of the scapula (Fig. 4.10).
2. Arm cannot be raised beyond 90° (i.e. overhead abduction which is performed by the serratus anterior is not possible).

Injury to Lateral Cord

Cause: Dislocation of humerus.

Nerves involved:
1. Musculocutaneous.
2. Lateral root of median.

Muscles paralysed:
1. Biceps and coracobrachialis.
2. All muscles supplied by the median nerve, except those of the hand.

Deformity and disability:
1. Midprone forearm.
2. Loss of flexion of forearm.
3. Loss of flexion of the wrist.
4. Sensory loss on the radial side of the forearm.
5. Vasomotor and trophic changes as above.

Injury to Medial Cord

Cause: Subcoracoid dislocation of humerus.

Nerves involved:
1. Ulnar.

Muscles paralysed:
1. Muscles supplied by ulnar nerve.
2. Five muscles of the hand supplied by the median nerve.

Deformity and disability:
1. Claw hand.
2. Sensory loss on the ulnar side of the forearm and hand.
3. Vasomotor and trophic changes as a bone.

Axillary Artery

Axillary artery is the continuation of the subclavian artery. It extends from the outer border of the first rib to the lower border of the teres major muscle. It continues as the brachial artery. Its direction varies with the position of the arm.

The pectoralis minor muscle crosses it and divides it into three parts (Fig. 4.11).

(i) First part, superior (proximal) to the muscle.
(ii) Second part, posterior (or deep) to the muscle.
(iii) Third part, inferior (distal) to the muscle.

Surface Marking

Hold the arm at right angles to the trunk with the palm directed upwards. The artery is then marked as a straight line by joining the following two points, (i) Midpoint of the clavicle (Fig. 4.12).
(ii) The second point at the junction of the anterior one-third and posterior two-thirds of the lateral wall of axilla at its lower limit where the arterial pulsations can be felt.

At its termination the axillary artery, along with the accompanying nerves, forms a prominence which lies behind another projection caused by the biceps and coracobrachialis.

Relations of First Part

Anteriorly

(i) Skin.

(ii) Superficial fascia, platysma and supraclavicular nerves.

(iii) Deep fascia.

(iv) Clavicular part of the pectoralis major.

(v) Clavipectoral fascia with cephalic vein, lateral pectoral nerve, and thoracoacromial vessels.

(vi) Loop of communication between the lateral and medial pectoral nerves.

Posteriorly

(i) First intercostal space with the external intercostal muscle.

(ii) First and second digitations of the serratus anterior with the nerve to serratus anterior.

(iii) Medial cord of brachial plexus with its medial pectoral branch (Fig. 4.13).

Laterally

Lateral and posterior cords of the brachial plexus.

Media

Axillary vein

The first part of the axillary artery is enclosed (together with the brachial plexus) in the axillary sheath, derived from the prevertebral layer of deep cervical fascia.

Relations of Second Part

Anteriorly

(i) Skin.
(i) Superficial fascia.
(ii) Deep fascia.
  (v) Pectoralis major.
(i) Pectoralis minor (Fig. 4.13).

Posteriorly

(i) Posterior cord of brachial plexus. (ii) Coracobrachialis.
Fig. 4.13: Relation of the brachial plexus to the axillary artery.

**Medially**

**Laterally**
Lateral cord of brachial plexus.

**Relations of Third Part**

**Anteriorly**
(i) Skin.
(ii) Superficial fascia, (iii) Deep fascia.
(iv) In the upper part there are the pectoralis major and medial root of the median nerve.

**Posteriorly**
(i) Radial nerve.
(ii) Axillary nerve in the upper part, (iii) Subscapularis in the upper part, (iv) Tendons of the latissimus dorsi and the teres major in the lower part.

**Laterally**
(i) Coracobrachialis.
(ii) Musculocutaneous nerve in the upper part, (iii) Lateral root of median nerve in the upper part, (iv) Trunk of median nerve in the lower part.
Hgi Upper Limb "^gBBBBBK/KKKEKM

Medially

(i) Axillary vein, (ii) Medial cutaneous nerve of the forearm and ulnar nerve, between the axillary artery and vein (Fig. 4.14). (iii) Medial cutaneous nerve of arm, medial to the axillary vein.

Branches of Axillary Artery

The axillary artery gives six branches. One branch arises from the first part, two branches from the second part, and three branches from the third part. These are as follows (Fig. 4.15).

7. Superior Thoracic Artery

Superior thoracic artery is a very small branch which may not be found during dissection. It arises from the first part of the axillary artery (near the subclavius), but may arise from the thoracoacromial artery. It runs downwards, forwards and medially, passes between the two pectoral muscles, and ends by supplying these muscles and the thoracic wall.

2. Thoracoacromial (Acromiothoracic) Artery

Thoracoacromial artery is a branch from the second part of the axillary artery. It emerges at the upper border of the pectoralis minor, pierces the clavipectoral fascia, and soon divides into four terminal branches: (a) the *pectoral branch* passes between the pectoral muscles, and supplies these muscles as well as the breast; (b) the *deltoid branch* runs in the deltopectoral groove, along with the cephalic vein; (c) The *acromial branch* (which may sometimes arise from the deltoid branch) crosses the coracoid process and ends by joining the anastomosis over the acromion; and (d) the *clavicular branch* runs superomedially deep to the pectoralis major, and supplies the sternoclavicular joint and subclavius.
3. Lateral Thoracic Artery

Lateral thoracic artery is a branch of the second part of the axillary artery. It emerges at, and runs along, the lower border of the pectoralis minor in close relation with the anterior group of axillary lymph nodes. In females, the artery is large and gives off the lateral mammary branches to the breast.

4. Subscapular Artery

Subscapular artery is the largest branch of the axillary artery, arising from its third part. It runs along the lower border of the subscapularis to terminate near the inferior angle of the scapula. It supplies the latissimus dorsi and the serratus anterior. It gives off a large branch, the circumflex scapular artery, which is larger than the continuation of the main artery. This branch passes through the triangular intermuscular space, winds round the lateral border of the scapula deep to the teres minor, and gives a branch to the Subscapular fossa (infraspinous branch), and another branch to the infraspinous fossa, both of which take part in the anastomosis round the scapula (Fig. 7.12).

5. Anterior Circumflex Humeral Artery

Anterior circumflex humeral artery is a small branch arising from the third part of the axillary artery, at the lower border of the subscapularis. It passes laterally in front of the intertubercular sulcus of the humerus, and anastomoses with the posterior circumflex humeral artery, to form an arterial circle round the surgical neck of the humerus. It gives off an ascending branch which runs in the intertubercular sulcus, and supplies the head of the humerus and shoulder joint.

6. Posterior Circumflex Humeral Artery

Posterior circumflex humeral artery is much larger than the anterior artery. It arises from the third part of the axillary artery at the lower border of the subscapularis, often close to its anterior counterpart. It runs backwards, accompanied by the axillary nerve, passes through the quadrangular intermuscular space, and ends by anastomosing with the anterior circumflex humeral artery round the surgical neck of the humerus (Fig. 7.6). It supplies the shoulder joint, the deltoid, and the muscles bounding the quadrangular space. It gives off a descending branch which anastomoses with the ascending branch of the profunda brachii artery.

Anastomosis and Collateral Circulation

The branches of the axillary artery anastomose with one another and with branches derived from neighbouring arteries (internal thoracic, intercostal, suprascapular, deep branch of transverse cervical, profunda brachii). When the axillary artery is blocked, a collateral circulation is established through the anastomosis round the scapula which links the first part of the subclavian artery with the third part of the axillary artery (apart from communications with the posterior intercostal arteries) (Fig. 7.12).

Variations

1. An additional 'alar thoracic' branch may arise from the second part of the axillary artery. This branch supplies axillary fat and lymph nodes.
2. Occasionally, the last three branches and the profunda artery may arise by a common trunk. In such cases, the branches of the brachial plexus surround this trunk instead of the axillary artery.
3. The posterior circumflex humeral artery may arise from the profunda artery. It then passes backwards below (not above) the teres major.
4. Sometimes the axillary artery divides into the radial and ulnar arteries, and occasionally gives off the anterior interosseous artery of the forearm.

Axillary Vein

The axillary vein is the continuation of the basilic vein. The axillary vein is joined by the venae comitantes of the brachial artery a little above the lower border of the teres major. It lies on the medial side of the axillary artery (Fig. 4.14). At the outer border of the first rib it becomes the subclavian vein. In addition to the tributaries corresponding to the branches of the axillary artery, it receives the cephalic vein in its upper part.

There is no axillary sheath around the vein, which is free to expand during times of increased blood flow. Occasionally amuscular band called the axillary arch overlies the vein. It may compress the vein and cause spontaneous thrombosis.

Axillary Lymph Nodes

The axillary lymph nodes are scattered in the fibrofatty tissue of the axilla. They are divided into five groups.

1. The nodes of the anterior (or pectoral) group lie along the lateral thoracic vessels (i.e. along the lower border of the pectoralis minor). These nodes are in direct contact with the axillary tail of the breast. They receive lymph from the upper half of the anterior wall of the trunk, and from the major part of the breast (Fig. 4.16).
2. The nodes of the *posterior (or scapular)* group lie along the Subscapular vessels, on the posterior fold.
of the axilla. They receive lymph from the posterior wall of the upper half of the trunk, and from the axillary tail of the breast.

1. The nodes of the lateral group lie along the upper part of the humerus, medial to the axillary vein. They receive lymph from the upper limb.

2. The nodes of the central group lie in the fat of the upper axilla. They receive lymph from the preceding groups and drain into the apical group. They receive some direct vessels from the floor of the axilla. The intercostobrachial nerve is closely related to them.

3. The nodes of the apical or infraclavicular group lie deep to the clavipectoral fascia, along the axillary vessels. They receive lymph from the central group, from the upper part of the breast, and from the thumb and its web. The lymphatics from the thumb accompany the cephalic vein.

CLINICAL ANATOMY

1. The axilla has abundant axillary hair. Infection of the hair follicles and sebaceous glands gives rise to boils which are common in this area.

2. The axillary lymph nodes drain lymph not only from the upper limb but also from the breast and the anterior and posterior body walls above the level of the umbilicus. Therefore, infections or malignant growths in any part of their territory can give rise to involvement of the axillary lymph nodes. Examination of these lymph nodes is therefore, important in clinical practice.

3. An abscess in the axilla may arise from infection and suppuration of particular groups of lymph nodes. Spread of the abscess is as usual, governed by the arrangement of the fascial planes and the fibrous sheaths.

When suppuration occurs superficial to the clavipectoral fascia, between the pectoral muscles, the pus points either at the anterior axillary fold, or in the deltopectoral groove. When suppuration takes place deep to the clavipectoral fascia, behind the pectoralis minor, the pus surrounds the neurovascular bundle and commonly ascends into the neck (this being the line of least resistance); but rarely it may descend along the vessels into the arm.

An axillary abscess should be incised through the floor of the axilla, midway between the anterior and posterior axillary folds, and nearer to the medial wall in order to avoid injury to the main vessels running along the anterior, posterior and lateral walls.

1. The axillary sheath is derived from the prevertebral layer of the deep cervical fascia. It encloses the axillary artery and the brachial plexus. Inferiorly it may extend up to the elbow. A cold abscess originating from the cervical vertebrae may track down through this sheath, and point on the lateral wall of the axilla along the course of the neurovascular bundle.

2. Axillary arterial pulsations can be felt against the lower part of the lateral wall of the axilla.

3. In order to check bleeding from the distal part of the limb (in injuries, operations and amputations) the artery can be effectively compressed against the humerus in the lower part of the lateral wall of the axilla.

4. Next to the popliteal artery, the axillary artery is the second most common artery of the body to be lacerated by violent movements. Occasionally, it is ruptured during reduction of an old dislocation of the shoulder.
This chapter deals mainly with structures which connect the upper limb with the back of the trunk.
SURFACE LANDMARKS

1. The scapula (or shoulder blade) is placed on the posterolateral aspect of the upper part of the thorax. It extends from the second to the seventh ribs. Although it is thickly covered by muscles most of its outline can be felt in the living subject. The acromion lies at the top of the shoulder. The crest of the spine of the scapula runs from the acromion medially and slightly downwards to the medial border of the scapula. The medial border and the inferior angle of the scapula can also be palpated (Fig. 5.1).

2. The eighth rib is just below the inferior angle of the scapula. The lower ribs can be identified on the back by counting down from the eighth rib.

3. The iliac crest is a curved bony ridge lying below the waist. The anterior end of the crest is the anterior superior iliac spine. The posterior superior iliac spine is felt in a shallow dimple above the buttock, about 5 cm from the median plane.

4. The sacrum lies between the right and left dimples mentioned above. Usually three sacral spines are palpable in the median plane.

5. The coccyx lies between the two buttocks in the median plane.

6. The spine of the seventh cervical vertebra or vertebra prominens is readily felt at the root of the neck. Higher up on the back of the neck the second cervical spine can be felt about 5 cm below the external occipital protuberance. Other spines that can be recognized are T3 at the level of root of the spine of the scapula, L4 at the level of the highest point of the iliac crest, and S2 at the level of the posterior superior iliac spine.
7. The junction of the back of the head with that of the neck is indicated by the external occipital protuberance and the superior nuchal lines. The external occipital protuberance is a bony projection felt in the median plane on the back of the head at the upper end of the nuchal furrow (running vertically on the back of the neck). The superior nuchal lines are
indistinct curved ridges which extend on either side from the protuberance to the mastoid process. The nuchal furrow extends to the external occipital protuberance, above, and to the spine of C7 below.

**SKIN AND FASCIAE OF THE BACK**

Man mostly lies on his back. Therefore, the skin and fasciae of the back are adapted to sustain pressure of the body weight. Accordingly, the skin is thick and fixed to the underlying fasciae; the superficial fascia containing variable amount of fat, is thick and strong and is connected to overlying skin by connective tissue; and the deep fascia is dense in texture.

**DISSECTION**

Identify the external occipital protuberance (i) of the skull. Draw a line in the midline from the protuberance to the spine of the last thoracic (T12) vertebra (ii). Make incision along this line (Fig. 5.1). Extend the incision from its lower end to the deltoid tuberosity (iii) on the humerus which is present on lateral surface about the middle of the arm. Note that the arm is placed by the side of the trunk. Make another incision along a horizontal line from seventh cervical spine (iv) to the acromion process of scapula (v).

**Cutaneous Nerves**

The cutaneous nerves of the back are derived from the posterior primary rami of the spinal nerves. Their distribution extends up to the posterior axillary lines. The following points may be noted:

1. The posterior primary rami of the spinal nerves C1, C7, C8, L4 and L5 do not give off any cutaneous branches. All twelve thoracic and five sacral nerves, however, give cutaneous branches (Figs 5.2, 5.3, 14.3).

2. Each posterior primary ramus divides into medial and lateral branches, both of which supply the erector spinae muscles, but only one of them, either medial or lateral, continues to become the cutaneous nerves. In the upper half of the body (up to T6), the medial branches, and in the lower half of the body (below T6) the lateral branches, of the posterior primary rami provide the cutaneous branches. Each cutaneous nerve divides into a smaller medial and a larger lateral branch before supplying the skin.

3. The posterior primary rami supply the intrinsic muscles of the back and the skin covering them. The cutaneous distribution extends further laterally than the extensor muscles.

4. No posterior primary ramus ever supplies skin or muscles of a limb. The cutaneous branches of the posterior primary rami of nerves L1, L2, L3 (S1-S3) are exceptions in this respect: they turn downwards unlike any other nerve and supply the skin of the gluteal region.

**MUSCLES CONNECTING THE UPPER LIMB WITH THE VERTEBRAL COLUMN**

Muscles connecting the upper limb with the vertebral column are the trapezius (Fig. 5.4), the latissimus dorsi, the levator scapulae, and the rhomboideus.
minor and rhomboideus major. The attachments of these muscles are given in Table 5.1, and their nerve supply and actions in Table 5.2.

DISSECTION

Identify the attachments of trapezius muscle in the upper part of back; and that of latissimus dorsi in the lower part. Cut vertically through trapezius 5 cm lateral to the vertebral spines. Divide the muscle horizontally between the clavicle and spine of scapula; and reflect it laterally to identify the accessory nerve and its accompanying blood vessels the superficial cervical artery.

Look for the suprascapular vessels and nerve, deep to trapezius muscle, towards the scapular notch. Cut through levator scapulae muscle midway between its two attachments and clean the dorsal scapular nerve (supplying the rhomboideus) and accompanying blood vessels. Identify rhomboideus minor from rhomboideus major muscle. Pull the medial or inner scapular border away from the chest wall for looking at the serratus anterior muscle. Define attachments of latissimus dorsi muscle.

A. Trapezius

1. Developmentally the trapezius is related to the sternocleidomastoid. Both of them develop from branchial arch mesoderm and are supplied by the spinal accessory nerve.

2. The principal action of the trapezius is to rotate the scapula during abduction of the arm beyond 90°. Clinically the muscle is tested by asking the patient to shrug his shoulder against resistance (Fig. 5.5).

<image src="Fig. 5.5: Test for trapezius muscle."/>

A large number of structures lies immediately un

cover of the trapezius. They are shown in Figs i 5.7 and 5.8 and are listed below.

C. Nerves
1. Spinal root of accessory nerve.
2. Suprascapular nerve.
3. C3, C4 nerves.
4. Posterior primary rami of C2-C6 and T1-T12 pierce the muscle to become cutaneous nerves.

D. Bursa
A bursa lies over the smooth triangular area at the root of the spine of the scapula.

Fig. 5.9: Rotation of the scapula during abduction of the arm beyond 90 degrees, brought about by the trapezius and the serratus anterior muscles.

6. Latissimus Dorsi
1. The latissimus dorsi develops in the extensor compartment of the limb. Thereafter it migrates to its wide attachment on the trunk, taking its nerve supply (thoracodorsal nerve) along with it.
2. It is developed in animals that suspend themselves by their arms (brachiators like apes, monkeys, etc.). The complexity of the muscle is indicated by the occasional presence in man of the
axillary arch and dorsoepitrochlearis brachii normally present in apes.

The axillary arch is a muscular slip which arises from the edge of the latissimus dorsi in the posterior fold of the axilla. It crosses the axilla in front of the vessels and nerves of the region and joins the tendon of the pectoralis major, or of the coracobrachialis or of the biceps. It is present in about 7% of subjects.

A fibrous or muscular slip may connect the lower border of the latissimus dorsi to the long head of the triceps. When muscular, it is called the dorsoepitrochlearis brachii.

3. The latissimus dorsi is tested clinically by feeling the contracting muscle in the posterior fold of the axilla after asking the patient to cough.

C. Triangle of Auscultation

Triangle of auscultation is a small triangular interval bounded medially by the lateral border of the trapezius, laterally by the medial border of the scapula, and inferiorly by the upper border of the latissimus dorsi. The floor of the triangle is formed by the seventh rib, sixth and seventh intercostal spaces, and the rhomboideus major. This is the only part of the back which is not covered with muscles. Respiratory sounds heard through a stethoscope are said to be better heard over this triangle than elsewhere on the back. On the left side, the cardiac orifice of the stomach lies deep to the triangle, and in days before X-rays were discovered the sounds of swallowed liquids were auscultated over this triangle.

D. Lumbar Triangle of Petit

Lumbar triangle of Petit is another small triangle surrounded by muscles. It is bounded medially by I the lateral border of the latissimus dorsi, laterally by the posterior border of the external oblique muscle of the abdomen, and inferiorly by the iliac crest (which forms the base). The occasional hernia at this site is called lumbar hernia.

After completing the dissection of the back, the limb with clavicle and scapula is detached from the trunk.

For detachment of the limb, muscles which need to be incised are trapezius, levator scapulae, rhomboideus minor and major, serratus anterior, latissimus dorsi and sternocleidomastoid. The sternoclavicular joint is opened to free clavicle from the sternum. Upper limb with clavicle and scapula are removed en bloc.

Additional Reading

Cutaneous Nerves, Superficial!

I Drainage of the Upper Limb I

The superficial fascia seen after the reflection of skin contains cutaneous nerves, cutaneous or superficial veins and lymphatics. The cutaneous nerves are the continuation of the spinal nerves and carry sympathetic fibres for supplying the sweat glands, arterioles in the dermis and arrector pilorum muscles in relation to the hair follicle. Thus, the effects of sympathetic on the skin are sudomotor, vasomotor and pilomotor respectively. The nerves also carry sensation of pain, touch, temperature and pressure. Superficial veins are seen along with the cutaneous nerves. These are utilised for giving intravenous transfusions, cardiac catheterisation and taking blood samples. Lymphatic vessels are not easily seen in ordinary dissection.

CUTANEOUS NERVES OF THE UPPER LIMB

The skin of the upper limb is supplied by 15 sets of cutaneous nerves (Table 6.1). Out of these only one set (supraclavicular) is derived from the cervical plexus, and another nerve (intercostobrachial) is derived from the second intercostal nerve. The remaining 13 sets are derived from the brachial plexus through the musculocutaneous, median, ulnar, axillary and radial nerves. Some branches arise directly from the medial cord of the plexus. It should be noted as follows:

(a) The areas of distribution of peripheral cutaneous nerves do not necessarily correspond with those of individual spinal segments. (Areas of the skin supplied by individual spinal segments are called dermatomes). This is so because each cutaneous nerve contains fibres from more than one ventral ramus (of a spinal nerve); and each ramus gives fibres to more than one cutaneous nerve.

(b) Adjacent areas of skin supplied by different cutaneous nerves overlap each other to a considerable extent. Therefore, the area of sensory loss after damage to a nerve is much less than the area of distribution of the nerve. The anaesthetic area is surrounded by an area in which the sensations are somewhat altered.

(c) In both the upper and lower limbs, the nerves of the anterior surface have a wider area of distribution than those supplying the posterior surface.

The individual cutaneous nerves, from above downwards, are described below with their root values. Figure 6.1 shows the cutaneous nerves of the upper limb.

1. The supraclavicular nerves (C3, C4) are branches of the cervical plexus. They pierce the deep fascia in the neck, descend superficial to the clavicle, and supply:

(a) the skin of the pectoral region up to the level of the second rib; and (b) skin covering the upper half of the deltoid.

2. The upper lateral cutaneous nerve of the arm (C5, C6) is the continuation of the posterior branch

DISSECTION

Give one horizontal incision in the arm at its junction of upper one-third and lower two-thirds segments (Fig. 3.2). Make a vertical incision through the centre of arm and forearm till the wrist where another transverse incision is given. Reflect the skin on either side on the front as well as on the back of the limb. Use this huge skin flap to cover the limb after the dissection.

Fig. 6.1: The cutaneous nerves of the upper limb.
of the axillary nerve. It pierces the deep fascia at the lower part of the posterior border of the deltoid, runs horizontally forwards, and supplies the skin covering the lower half of the deltoid and the upper part of the long head of the triceps.

1. The lower lateral cutaneous nerve of the arm (C5, C6) is a branch of the radial nerve given off in the radial groove. It perforates the lateral head of the triceps and then pierces the deep fascia just below the insertion of the deltoid. It supplies the skin of the lower half of the lateral side of the arm.

2. The intercostobrachial nerve (T2) is the lateral cutaneous branch of the second intercostal nerve. It crosses the axilla, pierces the deep fascia at the upper part of the medial side of the arm, and supplies the skin of the upper half of the medial and posterior parts of the arm. The size of this nerve is inversely proportional to that of the medial cutaneous nerve of the arm. A second intercostobrachial nerve (T3) may be present to reinforce the first one.

3. The medial cutaneous nerve of the arm (T1, T2) is the smallest branch of the medial cord of the brachial plexus. First it descends on the medial side of the axillary vein, and communicates with the intercostobrachial nerve. It then descends on the medial side of the basilic vein, pierces the deep fascia at the middle of the medial side of the arm, and supplies the skin of the lower half (or one-third) of the medial side of the arm. The intercostobrachial nerve may partially or completely replace this nerve.

4. The posterior cutaneous nerve of the arm (C5) is a branch of the radial nerve given off in the axilla. It crosses the intercostobrachial nerve posteriorly, pierces the deep fascia below the posterior fold of the axilla, and supplies the skin of the back of the arm from the insertion of the deltoid to the olecranon.

5. The lateral cutaneous nerve of the forearm (C5, C6) is the continuation of the musculocutaneous nerve. It pierces the deep fascia just lateral to the tendon of the biceps 2-3 cm above the bend of the elbow. It divides into anterior and posterior branches, and supplies the skin of the lateral side of the forearm, extending anteriorly to a small part of the ball of the thumb.

6. The medial cutaneous nerve of the forearm (C8, T1) is a branch of the medial cord of the brachial plexus. It runs along the medial side of the axillary and brachial arteries, pierces the deep fascia at the middle of the medial side of the arm (with the basilic vein) and supplies the skin of the medial side of the forearm. Near the axilla it gives off a filament which supplies the skin covering the biceps.

7. The posterior cutaneous nerve of the forearm (C6-C8) arises from the radial nerve, in the radial groove, in common with the lower lateral cutaneous
nerve of the arm. It perforates the lateral head of the triceps, and pierces the deep fascia a little below the middle of the forearm. After giving some branches to the lateral side of the arm, it descends posterior to the lateral epicondyle and supplies the skin of the back of the forearm.

10. The median nerve gives off two sets of cutaneous branches in the hand.

(a) The palmar cutaneous branch (C6-C8) arises a short distance above the wrist, pierces the deep fascia at the middle of the upper margin of the wrist and supplies skin over the lateral two-thirds of the palm including that over the thenar eminence.

(b) Palmar digital branches (C6-C8) are five in number and arise in the palm. The medial two branches are common palmar digital nerves; each divides near a digital cleft to form two proper palmar digital nerves. The lateral three branches are proper palmar digital nerves for the medial and lateral sides of the thumb and for the lateral side of the index finger. The two nerves for the thumb may have a common origin. The various digital branches of the median nerve supply palmar skin of the lateral three and a half digits, the nail beds, and skin on the dorsal aspect of the middle and distal phalanges of the same digits.

11. The ulnar nerve gives off three sets of cutaneous nerves in hand.

(a) The palmar cutaneous branch (C7, C8) arises in the middle of the forearm and descends over the ulnar artery. It pierces the deep fascia anterior to the wrist, and supplies skin of the medial one-third of the palm.

(b) The palmar digital branches of the ulnar nerve (C7, C8) are two in number. They arise from the superficial terminal branch of the ulnar nerve just distal to the pisiform bone. The medial of the two branches is a proper palmar digital nerve for the medial side of the little finger. The lateral branch is a common palmar digital nerve which divides into two proper digital nerves for supply of adjacent sides of the ring and little fingers.

(c) The dorsal branch of the ulnar nerve (C7, C8) arises about 5 cm above the wrist. It descends with the main trunk of the ulnar nerve almost to the pisiform bone. Here it passes backwards to divide into three (sometime two) dorsal digital nerves. Typically, the region of skin supplied by the dorsal branch covers the medial half of the back of the hand, and the skin on the dorsal aspect of the medial two and a half fingers. Sometimes the area is less (one-third of the back of the hand, and the medial one and a half fingers). Note that the terminal parts of the dorsal aspect of the digits are supplied by the median nerve as described above.
12. The superficial terminal branch of the radial nerve (C6-C8) arises in front of the lateral epicondyle of the humerus. It descends through the upper two-thirds of the forearm lateral to the radial artery, and then passes posteriorly about 7 cm above the wrist. While winding round the radius it pierces the deep fascia and divides into four or five small dorsal digital nerves. In all, the superficial terminal branch supplies the skin of the lateral half (sometimes two-thirds) of the dorsum of the hand, and the dorsal surfaces of the lateral two and a half (sometimes three and a half) digits including the thumb, except for the terminal portions supplied by the median nerve.

THE DERMATOMES OF THE UPPER LIMB

**Definition:** The area of skin supplied by one spinal segment is called a dermatome. A typical dermatome extends from the posterior median line to the anterior median line on the side of the trunk (Fig. 5.2). However, in the limbs the dermatomes have migrated rather irregularly, so that the original uniform pattern is disturbed.

**Embryological Basis**

The early human embryo shows regular segmentation of the body. Each segment is supplied by the corresponding segmental nerve. In an adult, all structures, including the skin, developed from one segment, are supplied by their original segmental nerve. The limb may be regarded as an extension of the body wall, and the segments from which they are derived can be deduced from the spinal nerves supplying them. The limb buds arise in the area of the body wall supplied by the lateral branches of anterior primary rami. The nerves to the limbs represent these branches (Fig. 6.2).

**Important Features**

1. The cutaneous innervation of the upper limb is derived:
   (a) Mainly from segments C5-C8 and T1 of the spinal cord, and
   (b) partly from the overlapping segments from above (C3, C4) as well from below (T2, T3). The additional segments are found only at the proximal end of the limb (Fig. 6.3).
2. Since the limb bud appears on the ventrolateral aspect of the body wall, it is invariably supplied by the anterior primary rami of the spinal nerves. Posterior primary rami do not supply the limb.

*Fig. 6.2: The body wall is supplied by (A) the posterior primary rami, (B) the lateral branches of the anterior primary rami, arm (C) the anterior branches of the anterior primary rami of the spinal nerves. The limb buds develop from the area supplied by the lateral branches of the anterior primary rami.*

*Fig. 6.3: The upper limb bud grows out opposite segments C5, C6, C7, C8 and T1 of the spinal cord.*

It is possible that the ventral and dorsal divisions of the trunks of the brachial plexus represent the anterior and posterior branches of the lateral cutaneous nerves (Figs 6.4, 4.7, 5.2).

1. There is varying degree of overlapping of adjoining dermatomes, so that the area of sensory loss following damage to the cord or nerve roots is always less than the area of distribution of the dermatomes (Fig. 6.5).
2. Each limb bud has a cephalic and a caudal border, known as preaxial and postaxial borders, respectively. In the upper limb, the thumb and radius lie along the preaxial border, and the little finger and ulna along the postaxial border.
3. The dermatomes of the upper limb are distributed in an orderly numerical sequence (Fig. 6.6).
   (i) Along the preaxial border from above downward, by segments C3-C6.
(ii) The middle three digits (index, middle and ring fingers) and the adjoining area of the palm are supplied by segment C7. (iii) The postaxial border is supplied (from below upwards) by segments C8, T1, T2. 6. As the limb elongates, the central dermatomes (C6-C8) get pulled in such a way that these are represented only in the distal part of the limb, and are buried proximally. The line along which the central dermatomes are buried (missing) and distant dermatomes adjoin each other, and across which the overlapping of the dermatomes is minimal is called the axial line. There are two axial lines, ventral and dorsal. The ventral axial line extends down almost up to the wrist, whereas the dorsal axial line extends only up to the elbow.

**CLINICAL ANATOMY**

The area of sensory loss of the skin, following injuries of the spinal cord or of the nerve roots, conforms to the dermatomes. Therefore, the segmental level of the damage to the spinal cord can be determined by examining the dermatomes for touch, pain, and temperature. Note that injury to a peripheral nerve produces sensory loss corresponding to the area of distribution of that nerve. The spinal segments do not lie opposite the corresponding vertebrae. In estimating the position of a spinal segment in relation to the surface of the body it is important to remember that a vertebral spine is always lower than the corresponding spinal segment. As a rough guide it may be stated that in the cervical region there is a difference of one segment, e.g. the 5th cervical spine overlies the 6th cervical spinal segment.

**THE SUPERFICIAL VEINS**

Superficial veins of the upper limb assume importance in medical practice because these are most commonly used for intravenous injections and for withdrawing blood for transfusion or for testing.

**General Remarks**

1. Most of the superficial veins of the limb join together to form two large veins, cephalic (preaxial) and basilic (postaxial). An accessory cephalic vein is often present.
2. The superficial veins run away from pressure points. Therefore, they are absent in the palm (fist area), in the ulnar border of the forearm (supporting border) and in the back of the arm and trapezius region (resting surface). This makes the course of the...
veins spiral, from the dorsal to the ventral surface of the limb.

1. The preaxial vein is longer than the postaxial. In other words, the preaxial vein drains into the deep (axillary) vein more proximally (at the root of the limb) than the postaxial vein which becomes deep in the middle of the arm.

2. The earlier a vein becomes deep the better because the venous return is then assisted by muscular compression. The load of the preaxial (cephalic) vein is greatly relieved by the more efficient postaxial (basilic) vein through a short circuiting channel (the median cubital vein situated in front of the elbow) and partly also by the deep veins through a perforator vein connecting the median cubital with the deep vein.

3. The superficial veins are accompanied by cutaneous nerves and superficial lymphatics, and not by arteries. The superficial lymph nodes lie along the veins, and the deep lymph nodes along the arteries.

4. The superficial veins are best utilised for intravenous injections.

Individual Veins

Dorsal Venous Arch

Dorsal venous arch lies on the dorsum of the hand (Fig. 6.7). Its afferents (tributaries) include: (i) three dorsal metacarpal veins, (ii) a dorsal digital vein from the medial side of the little finger, (iii) a dorsal digital! vein from the radial side of the index finger, (iv) two I dorsal digital veins from the thumb, and (v) most of! the blood from the palm through veins passing! around the margins of the hand and also by perforating veins passing through the interosseous I spaces. Pressure on the palm during gripping fails to I impede the venous return due to the mode of drainageH of the palm into the dorsal venous arch. Its efferent™ are the cephalic and basilic veins.

Cephalic Vein

Cephalic vein is the preaxial vein of the upper limb (cf. great saphenous vein of the lower limb).

It begins from the lateral end of the dorsal venous arch.

It runs upwards: (i) through the roof of the anatomic snuffbox, (ii) winds round the lateral border! of the distal part of the forearm, (iii) continues I upwards in front of the elbow and along the lateral I border of the biceps brachii, (iv) pierces the deep I fascia at the lower border of the pectoralis major, (v) runs in the deltopectoral groove up to the infraclavicular fossa, where (vi) it pierces the clavicular fascia and joins the axillary vein.

At the elbow, the greater part of its blood is drained into the basilic vein through the median cubital vein,
and partly also into the deep veins through the perforator vein. It is accompanied by the lateral cutaneous nerve of the forearm, and the terminal part of the radial nerve. An accessory cephalic vein is sometimes present. It ends by joining the cephalic vein near the elbow.

Basilic Vein

Basilic vein is the postaxial vein of the upper limb (cf. short saphenous vein of the lower limb).
It begins from the medial end of the dorsal venous arch. It runs upwards: (i) along the back of the medial border of the forearm, (ii) winds round this border near the elbow, (iii) continues upwards in front of the elbow (medial epicondyle) and along the medial margin of the biceps brachii up to the middle of the arm where (iv) it pierces the deep fascia, and (v) runs along the medial side of the brachial artery up to the lower border of teres major where it becomes the axillary vein.

About 2.5 cm above the medial epicondyle of the humerus, it is joined by the median cubital vein. It is accompanied by the posterior branch of the medial cutaneous nerve of the forearm and the terminal part of the dorsal branch of the ulnar nerve.

Median Cubital Vein
Medial cubital vein is a large communicating vein which shunts blood from the cephalic to the basilic vein.

It begins from the cephalic vein 2.5 cm below the bend of the elbow, runs obliquely upward and medially, and ends in the basilic vein 2.5 cm above the medial epicondyle. It is separated from the brachial artery by the bicipital aponeurosis.

It may receive tributaries from the front of the forearm (median vein of the forearm) and is connected to the deep veins through a perforator vein which pierces the bicipital aponeurosis. The perforator vein fixes the median cubital vein and thus makes it ideal for intravenous injections.

Median Vein of the Forearm
Median vein of the forearm begins from the palmar venous network, and ends in any one of the veins in front of the elbow. Sometimes it divides into median cephalic and median basilic veins which join the cephalic and basilic veins respectively; this pattern replaces the median cubital vein. Variations in cubital veins

1. The cephalic and basilic veins are connected by the median cubital vein in 70% of subjects (Fig. 6.8A).
2. The whole cephalic vein drains into the basilic vein in 20% of cases (Fig. 6.8B).
3. The cephalic and basilic veins remain separate in 10% of subjects (Fig. 6.8C). For further details of variations see Fig. 6.8.
preferred over the cephalic because the former is a more efficient channel.

2. The cephalic vein frequently communicates with the external jugular vein by means of a small vein which crosses in front of the clavicle. In operations for removal of the breast (in carcinoma), the axillary lymph nodes are also removed, and it sometimes becomes necessary to remove a segment of the axillary vein also. In these cases, the communication between the cephalic vein and the external jugular vein enlarges considerably and helps in draining blood from the upper limb.

In case of fracture of the clavicle, the rupture of the communicating channel may lead to formation of a large haematoma, i.e. collection of blood.

LYMPH NODES AND LYMPHATIC DRAINAGE

When circulating blood reaches the capillaries, part of its fluid content passes through them into the surrounding tissue as tissue fluid. Most of this tissue fluid re-enters the capillaries at their venous ends. Some of it is, however, returned to the circulation through a separate set of lymphatic vessels. These vessels begin as lymphatic capillaries which drain into larger vessels. Along the course of these lymph vessels there are groups of lymph nodes. Lymph vessels are difficult to see and special techniques are required for their visualization. Lymph nodes are small bean-like structures that are usually present in groups. These are not normally palpable in the living subject. However, they often become enlarged in disease, particularly by infection or by malignancy in the area from which they receive lymph. They then become palpable and examination of these nodes provides valuable information regarding the presence and spread of disease. It is, therefore, of importance for the medical student to know something of the lymphatic drainage of the different parts of the body.

Lymph Nodes

The main lymph nodes of the upper limb are the axillary lymph nodes. These have been described in Chapter 4. Other nodes are as follows.

1. The infraclavicular nodes lie in or on the clavipectoral fascia along the cephalic vein. They drain the upper part of the breast, and the thumb with its web.

2. The deltopectoral node lies in the deltopectoral groove along the cephalic vein. It is a displaced node of the infraclavicular set, and drains similar structures.

1. The superficial cubital or supratrochlear nodes lie just above the medial epicondyile along the basilic I vein. They drain the ulnar side of the hand and forearm.

2. A few other deep lymph nodes lie in the following regions:
   (i) along the medial side of the brachial artery; (ii) at the bifurcation of the brachial artery (deep cubital lymph node); and (iii) occasionally along the arteries of the forearm.

Lymphatics

Superficial Lymphatics

Superficial lymphatics are much more numerous than the deep lymphatics. They collect lymph from the skin and subcutaneous tissues. Most of them ultimately drain into the axillary nodes, except for: (i) a few vessels from the medial side of the forearm which drain into the superficial cubital nodes, and (ii) a few vessels from the lateral side of the forearm which drain into the deltopectoral or infraclavicular nodes.

The dense palmar plexus drains mostly into the lymph vessels on to the dorsum of the hand, where these continue with the vessels of the forearm. Lymph vessels of the back of forearm and arm curve round their medial and lateral surfaces ascend up to reach the floor of the axilla. Thus there is a vertical area of 'lymphshed' in the middle of back of forearm and arm (Fig. 6.9).

Deep Lymphatics

Deep lymphatics are much less numerous than the superficial lymphatics. They drain structures lying deep to the deep fascia. They run along the main blood vessels of the limb, and end in the axillary nodes. Some of the lymph may pass through the deep lymph nodes present along the axillary vein as mentioned above (Figs 6.10, 6.11).

CLINICAL ANATOMY

1. Inflammation of lymph vessels is known as lymphangitis. In acute lymphangitis, the vessels may be seen through the skin as red, tender (= painful to touch) streaks.

2. Inflammation of lymph nodes is called lymphadenitis. It may be acute or chronic. The nodes enlarge and become palpable and painful.

3. Obstruction to lymph vessels can result in accumulation of tissue fluid in areas of drainage.
**Fig. 6.9:** The superficial lymphatics of the upper limb.

**Fig. 6.10:** Lymph nodes in relation to walls of the axilla.

**Fig. 6.11:** Lymph nodes in relation to the axillary vein.
This is called lymphoedema. This may be caused by carcinoma, infection with some parasites like
... i <i t.
ilenas, or because of surgical removal of lymph nodes.

References and Additional Reading

The shoulder or scapular region comprises structures which are closely related to and surround the shoulder joint. For a proper understanding of the region, revise some features of the scapula and the upper end of the humerus. Note the following:

1. **SURFACE LANDMARKS**

   1. Following bony landmarks are palpable:
      (a) The acromion, crest of the spine, its medial and lateral borders, and inferior angle of the scapula can be felt through the skin (Fig. 7.1).

      (b) The upper half of the humerus is covered on its anterior, lateral and posterior aspects by the deltoid muscle. This muscle is triangular in shape and forms the rounded contour of the shoulder.

      (c) The greater tubercle of the humerus forms the most lateral bony point of the shoulder.

   2. The skin covering the shoulder region is supplied by:

      (a) The lateral supraclavicular nerve, over the upper half of the deltoid;

      (b) the upper lateral cutaneous nerve of the arm, over the lower half of the deltoid; and

      (c) the dorsal rami of the upper thoracic nerves, over the back, i.e., over the scapula.

   1. The superficial fascia contains (in addition to moderate amounts of fat and cutaneous nerves) the inferolateral part of the platysma arising from the deltoid fascia.

   2. The deep fascia covering the deltoid sends numerous septa between its fasciculi. The sub-scapularis, supraspinatus and infraspinatus fasciae provide origin to a part of the respective muscle.

**MUSCLES OF THE SCAPULAR REGION**

These are the deltoid, the supraspinatus, the infraspinatus, the teres minor, the subscapularis, and the teres major. The deltoid is described below. The other muscles are described in Tables 7.1 and 7.2.

**The Deltoid**

**Origin**

1. The anterior border of the lateral one-third of the clavicle (Fig. 7.2).

2. The lateral border of the acromion.

3. Lower lip of the crest of the spine of the scapula.

Insertion

The deltoid tuberosity of the humerus.

Nerve Supply Axillary nerve (C5, C6).

Structure

The acromial part of deltoid is an example of a multipennate muscle. Many fibres arise from four septa of origin that are attached above to the acromion. The fibres converge on to three septa of insertion which are attached to the deltoid tuberosity (Fig. 7.2). A multipennate arrangement allows a large number of muscle fibres to be packed into a relatively small volume. As the strength of contraction of a muscle is proportional to the number of muscle fibres present in it (and not on their length), a multipennate muscle is much stronger than other muscles having the same volume.

Actions

1. The acromial fibres are powerful abductors of the arm at the shoulder joint from 15°-90°.
2. The anterior fibres are flexors and medial rotators of the arm.
3. The posterior fibres are extensors and lateral rotators of the arm.

Structures Under Cover of the Deltoid

Bones

(i) The upper end of the humerus, (ii) The coracoid process.
Fig. 7.2: The origin and insertion of the deltoid muscle.
Muscles

Insertions of

(i) Pectoralis minor on coracoid process. (ii) Supraspinatus, infraspinatus, and teres minor (on the greater tubercle of the humerus) (Fig. 7.3). (iii) Subscapularis on lesser tubercle of humerus (Fig. 7.4).
(iv) Pectoralis major, teres major and latissimus dorsi on the intertubercular sulcus of the humerus (Fig. 7.5).

Origin of:

(i) Coracobrachialis and short head of biceps from the coracoid process.
(ii) Long head of the biceps from the supraglenoid tubercle.
(iii) Long head of the triceps from the infraglenoid tubercle.
(iv) The lateral head of the triceps from the upper end of the humerus.
Fig. 7.5: Horizontal section of the deltoid region showing arrangement of the muscles in and around the bicpital groove.

Vessels

(i) Anterior circumflex humeral, (ii) Posterior circumflex humeral (Fig. 7.6).

Nerve

Axillary (Fig. 7.6).

Fig. 7.6: Horizontal section of the deltoid region showing the nerves and vessels around the surgical neck of humerus.

Joints and Ligaments

(i) Musculotendinous cuff of the shoulder (Fig. 7.7). (ii) Thoroacoacromial ligament.

Bursae

All bursae around the shoulder joint, including the subacromial or subdeltoid bursa (Figs 7.8, 7.9).
DISSECTION

Define the margins of the deltoid muscle covering the shoulder joint region (Fig. 7.10). Reflect the part of the muscle arising from spine of scapula downwards. Separate the infraspinatus muscle from teres major and minor muscles which run from the lateral scapular border towards humerus. Axillary nerve accompanied with posterior circumflex humeral vessels lies on the deep aspect of the deltoid muscle. These structures should be traced towards quadrangular intermuscular space; through which these pass. The quadrangular space is bounded by teres minor above and teres major below; by the long head of triceps muscle medially and the surgical neck of humerus laterally. Identify the nerve to the teres minor muscle.

Another intermuscular space, the upper triangular space should be dissected. It is bounded by the lateral border of scapula medially, long head of triceps laterally, and teres major muscle below. Now the remaining two-thirds of deltoid muscle can be reflected towards its insertion. Identify subscapularis muscle anteriorly. Define the attachments. Cut through the infraspinatus muscle at the neck of scapula and reflect it on both sides. Dissect and identify the arteries taking part in the anastomosis around scapula. These are suprascapular along upper border, deep branch of transverse cervical (dorsal scapular) along medial border and circumflex scapular along lateral border of scapula. Look for the structures covered with deltoid muscle.

Identify a lower triangular space which is bounded above by the lower border of teres major muscle, medially by the long head and laterally by the lateral head of triceps brachii muscle. The radial nerve and profunda brachii vessels pass through the space.

Musculotendinous Cuff of the Shoulder or Rotator cuff

Musculotendinous cuff of the shoulder is a fibrous sheath formed by the four flattened tendons which blend with the capsule of the shoulder joint and strengthen it. The muscles which form the cuff arise from the scapula and are inserted into the lesser and greater tubercles of the humerus. They are the subscapularis, the supraspinatus, the infraspinatus and the teres minor (Fig. 7.11). Their tendons, while crossing the shoulder joint, become flattened and blend with each other on one hand, and with the capsule of the joint on the other hand, before reaching their points of insertion.

The cuff gives strength to the capsule of the shoulder joint all around except interiorly. This explains why dislocations of the humerus occur most commonly in a downward direction.

Subacromial Bursa

Subacromial bursa is the largest bursa of the body, situated below the coracoacromial arch and the deltoid muscle. Below the bursa there are the tendon of the supraspinatus and the greater tuberosity of the humerus (Figs 7.8, 7.9).

The subacromial bursa is of great value in the abduction of the arm at the shoulder joint, (i) It protects the supraspinatus tendon against friction with the acromion, (ii) During overhead abduction the greater tuberosity of the humerus passes under the acromion: this is facilitated by the presence of this bursa.

CLINICAL ANATOMY

1. Intramuscular injections are often given into the deltoid. They should be given in the lower half of the muscle to avoid injury to the axillary nerve.
2. The deltoid muscle is tested by asking the patient to abduct the arm against resistance applied with one hand, and feeling for the contracting muscle with the other hand.
3. In subacromial bursitis, pressure over the deltoid below the acromion with the arm by the side causes pain. However, when the arm is abducted pressure over the same point causes no pain, because the bursa disappears under the acromion (Dawbarn's sign). Subacromial or subdeltoid bursitis is usually secondary to inflammation of the supraspinatus tendon. In this condition there is pain in the shoulder on abduction and medial rotation of the arm.
4. The tendon of the supraspinatus may undergo degeneration. This can give rise to calcification and even spontaneous rupture of the tendon.

Intermuscular Spaces

Three intermuscular spaces are to be seen in the scapular region (Figs 7.10, 7.11). These are:
Quadrangular Space

Boundaries: Superior.
(i) Subscapularis in front, (ii) Capsule of the shoulder joint, (iii) Teres minor behind. Inferior. Teres major.
Upper Triangular Space

Boundaries:  
- Medial. Teres minor.
- Lateral. Long head of the triceps.
- Inferior. Teres major.

Contents:  Circumflex scapular artery. It interrupts the origin of the teres minor and reaches the infraspinous fossa for anastomosis with the suprascapular artery.

Lower Triangular Space

Boundaries:  
- Medial. Long head of the triceps.
- Lateral. Medial border of humerus.
- Superior. Teres major.

Contents:  
(i) Radial nerve.
(ii) Profunda brachii vessels.

AXILLARY OR CIRCUMFLEX NERVE

Axillary or circumflex nerve is an important nerve because it supplies the deltoid muscle which is the main abductor of the arm. Surgically it is important, because it is commonly involved in dislocations of the shoulder and in fractures of the surgical neck of the humerus.

The axillary nerve is a branch of the posterior cord of the brachial plexus (C5, C6).

Surface Marking

Axillary or circumflex nerve is marked as a horizontal line on the deltoide muscle, 2 cm above the midpoint between the tip of the acromion process and the insertion of the deltoide (Fig. 8.21).

Intramuscular injections in the deltoide are given in the lower part of the muscle nearer to its insertion to avoid injury to the nerve and its accompanying vessels.

Root Value

Its root value is ventral rami of cervical 5, 6 segments of spinal cord.

Course and Relations

(A) In the lower part of the axilla, the nerve runs downwards behind the third part of the axillary artery. Here it lies on the subscapularis muscle. It is related medially to the median nerve, and laterally to the coracobrachialis.

The nerve leaves the axilla by winding round the lower border of the subscapularis in close relation to the lowest part of the capsule of the shoulder joint, and enters the quadrangular space.

(B) The nerve then passes backwards through the quadrangular space. Here it is accompanied by the posterior circumflex humeral vessels and has the following relations (Figs 7.10, 7.11).

Superiorly

(i) Subscapularis.
(ii) Lowest part of the capsule of the shoulder joint, (iii) Surgical neck of humerus (Fig. 7.6).

Interiorly Teres major.

Medially

Long head of the triceps.

In the quadrangular space, the nerve divides into anterior and posterior branches in relation to the deltoid muscle (Fig. 7.6).

(C) The anterior branch is accompanied by the posterior circumflex humeral vessels. It winds round the surgical neck of the humerus, deep to the deltoid, reaching almost up to the anterior border of the muscle. It supplies the deltoid and the skin over its anteroinferior part.

(D) The posterior branch supplies the teres minor and the posterior part of the deltoid. The nerve to the teres minor bears a pseudoganglion, fibrous tissue
and fat without any neurons (Fig. 7.10). The posterior branch then pierces the deep fascia at the lower part of the posterior border of the deltoid and continues as the upper lateral cutaneous nerve of the arm.

**Branches and Distribution**

**Muscular**
To the deltoid and the teres minor. The nerve to the teres minor bears a pseudoganglion.

**Cutaneous**
The upper lateral cutaneous nerve of the arm supplies the skin covering the lower half of the deltoid and the upper part of the long head of the triceps (Fig. 6.1).

**Articular**
An articular branch is given to the shoulder joint. The branch arises from the trunk of the axillary nerve and enters the joint just below the subscapularis.

**Vascular**
Sympathetic fibres along the axillary nerve supply the posterior circumflex humeral artery.

**CLINICAL ANATOMY**
The axillary nerve may be damaged by dislocation of the shoulder or by the fracture of the surgical neck of the humerus. The effects produced are: (i) Deltoid is paralysed, with loss of the power of abduction up to 90° at the shoulder, (ii) The rounded contour of the shoulder is lost, and the greater tubercle of the humerus becomes prominent. (iii) There is sensory loss over the lower half of the deltoid.

**ANASTOMOSIS AROUND THE SCAPULA**
Anastomoses around the body of the scapula. The anastomoses occur in the three fossae: subscapular, supraspinous and infraspinous. It is formed by:
(a) The suprascapular artery, a branch of the thyrocervical trunk;
(b) the deep branch of the transverse cervical artery, another branch of the thyrocervical trunk;
(c) the circumflex scapular artery, a branch of the subscapular artery which arises from the third part of the axillary artery.

Note that this is an anastomosis between the first part of the subclavian artery and the third part of the axillary artery.

**Anastomoses over the acromion process**
It is formed by:
(a) The acromial branch of the thoracoacromial artery;
(b) the acromial branch of the suprascapular artery; and
(c) the acromial branch of the posterior circumflex humeral artery.

Note that this also is an anastomosis between the first part of the subclavian artery and the third part of the axillary artery (Fig. 7.12).

**CLINICAL ANATOMY**
These anastomoses provide a collateral circulation through which blood can flow to the limb when the distal part of the subclavian artery, or the proximal part of the axillary artery is blocked. The shoulder girdle and the shoulder joint are parts of the scapular region. They are described in Chapter 10.

**Additional Reading**
The arm extends from the shoulder joint till the elbow joint. The skeleton of the arm is a 'solo' bone, the humerus. Medial and lateral intermuscular septa divide the arm into an anterior or flexor compartment and a posterior or extensor compartment, to give each compartment its individuality and freedom of action. Since the structures in the front of arm continue across the elbow joint into the cubital fossa, the cubital fossa is also included in this chapter. The arm is called brachium, so most of the structures in this chapter are named accordingly, like brachialis, coracobrachialis and brachial artery.
THE FRONT OF THE ARM

SURFACE LANDMARKS

The following landmarks can be felt in the living subject.

1. The greater tubercle of the humerus is the most lateral bony point in the shoulder region. It can be felt just below the acromion, deep to the deltoid when the arm is by the side of the trunk (Fig. 8.1).

2. The shaft of the humerus is felt only indistinctly because it is surrounded by muscles in its upper half. In the lower half, the humerus is covered anteriorly by the biceps and brachialis, and posteriorly by the triceps.

3. The medial epicondyle of the humerus is a prominent bony projection on the medial side of the elbow. It is best seen and felt in a midflexed elbow.

4. The lateral epicondyle of the humerus is less prominent than the medial. It can be felt in the upper part of the depression on the posterolateral aspect of the elbow in the extended position of the forearm.

5. The medial and lateral supracondylar ridges are better defined in the lower portions of the medial
and lateral borders of the humerus. They can be felt in the lower one-fourth of the arm as upwards continuations of the epicondyles.

1. The **deltoid** forms the rounded contour of the shoulder. The apex of the muscle is attached to the deltoid tuberosity located at the middle of the anterolateral surface of the humerus.

2. The **coracobrachialis** forms an inconspicuous rounded ridge in the upper part of the medial side of the arm. Pulsations of the brachial artery can be felt, and often seen, in the depression behind it.

3. The **biceps brachii** muscle is overlapped above by the pectoralis major and by the deltoid. Below these muscles the biceps forms a conspicuous elevation on the front of the arm. Upon flexing the elbow the contracting muscles becomes still more prominent. The tendon of the biceps can be felt in front of the elbow. The tendon is a guide to the brachial artery which lies on the its medial side.
9. The brachial artery can be felt in front of the elbow joint just medial to the tendon of the biceps. Brachial pulsations are used in recording the blood pressure.

1. The ulnar nerve can be rolled by the palpating finger behind the medial epicondyle of the humerus.

2. The superficial cubital veins can be made more prominent by applying tight pressure round the arm and then contracting the forearm muscles by clenching and unclenching the fist a few times. The cephalic vein runs upwards along the lateral border of the biceps. The basilic vein can be seen along the lower half of the medial border of the biceps. The cephalic and basilic veins are connected together in front of the elbow by the median cubital vein which runs obliquely upwards and medially.

COMPARTMENTS OF THE ARM

The arm is divided into anterior and posterior compartments by extension of deep fascia which are called the medial and lateral intermuscular septa (Fig. 8.2). These septa provide additional surface for the attachment of muscles. They also form planes along which nerves and blood vessels travel. The septa are well defined only in the lower half of the arm and are attached to the medial and lateral borders and supracondylar ridges of the humerus. The medial septum is pierced by the ulnar nerve and the superior ulnar collateral artery; the lateral septum is pierced by the radial nerve and the anterior descending branch of the profunda brachii artery.

Two additional septa are present in the anterior compartment of the arm. The transverse septum separates the biceps from the brachialis and encloses the musculocutaneous nerve. The anteroposterior septum separates the brachialis from the muscles attached to the lateral supracondylar ridge; it encloses the radial nerves and the anterior descending branch of the profunda brachii artery.

MUSCLES OF THE ANTERIOR COMPARTMENT OF THE ARM

Muscles of the anterior compartment of the arm are the coracobrachialis, the biceps brachii and the brachialis. They are described in Tables 8.1 and 8.2. Some additional points about the muscles are given:

DISSECTION

Make an incision in the middle of deep fascia of the upper arm right down up to the elbow joint. Reflect the flaps sideways. The most prominent muscle seen is the biceps brachii. Deep to this, another muscle called brachialis is seen easily. In the fascial septum between the two muscles lies the musculocutaneous nerve (a branch of the lateral cord of brachial plexus). Trace the tendinous long head of biceps arising from the supraglenoid tubercle and the short head arising from the tip of the coracoid process of scapula. Identify coraco-brachialis muscle on the medial side of biceps. Clean the branches of the nerve supplying all the three muscles dissected.

Additional Points about the Coracobrachialis

1. The muscle is pierced by the musculocutaneous nerve.
2. Morphologically it represents the medial compartment of the arm.
3. Its insertion is an important landmark; many transitions occur at this level.

Changes at the level of Insertion of Coracobrachialis

1. Bone: The circular shaft becomes triangular below this level.
2. Fascial septa: The medial and lateral intermuscular septa become better defined from this level down.
3. Muscles
   (i) Deltoid is inserted at this level, (ii) Upper end of origin of brachialis, (iii) Upper end of origin of the medial head of triceps.
4. Arteries
   (i) The brachial artery passes from the medial side of the arm to its anterior aspect.
   (ii) The profunda brachii artery runs in the spiral groove and divides into its anterior and posterior descending branches.
   (iii) The superior ulnar collateral artery originates from the brachial artery, and pierces I the medial intermuscular septum with the ulnar nerve.
   (iv) The nutrient artery of the humerus enters I the bone.

Veins
(i) The basilic vein pierces the deep fascia.
(ii) Two venae comitants of the brachial artery may unite to form one brachial vein.

6. Nerves
   (i) The median nerve crosses the brachial artery from the lateral to the medial side.
   (ii) The ulnar nerve pierces the medial intermuscular septum with the superior ulnar collateral artery and goes to the posterior compartment.
   (iii) The radial nerve pierces the lateral intermuscular septum with the anterior descending (radial collateral) branch of the profunda brachii artery and passes from the posterior to the anterior compartment.
   (iv) The medial cutaneous nerve of the arm pierces I the deep fascia.
   (v) The medial cutaneous nerve of the forearm I pierces the deep fascia.

Morphology of Coracobrachialis

The muscle is more important morphologically than functionally. It represents the medial compartment of the arm which is so well developed in the thigh. In some animals, the muscle is bicipital. In man, the upper two heads have fused, but the musculocutaneous nerve passes between the remnants of these two heads. The third and lowest head of the muscle has disappeared in man. Occasional persistence of the lower head is associated with the presence of the so called 'ligament of Struthers' which is a fibrous band extending from the trochlear spine to the medial epicondyle of the humerus. The third head of the coracobrachialis is inserted into this ligament. The lower part of the pronator teres muscle takes origin from the same ligament. The median nerve, or the brachial artery, or both pass subjacent to the ligament. The ligament of Struthers is, in fact, a part of the tendon of the dorsoepitrochlearis which is related to the latissimus dorsi.

The front or anterior compartment of the arm is homologous with the posterior and medial
compartments of the thigh. The flexor compartment of the thigh faces posteriorly because the lower limb rotates (during development) in a direction opposite to that of the upper limb. The medial (adductor) compartment of the arm has degenerated phylogenetically and is represented only by the coracobrachialis. However, the arm can be powerfully adducted by the large muscles in the anterior and posterior walls of the axilla, namely, the pectoralis major and the latissimus dorsi.

Additional Points about Biceps Brachii

1. Additional heads of biceps
(a) When present, the third head of the biceps arises from the upper and medial part of the brachialis, passes behind the brachial artery, and is inserted on the bicipital aponeurosis and the medial side of the bicipital tendon. At times the third head consists of two slips which pass in front and behind the brachial artery.
(b) A fourth head may arise from the lateral side of the humerus, or from the intertubercular sulcus.
(c) Other additional heads may occur.

2. Bicipital aponeurosis: This is a broad tendinous expansion from the medial side of the tendon of the biceps given off at the level of the bend of the elbow. It passes obliquely downwards and medially, crosses the brachial artery and fuses with the deep fascia covering the origin of flexors of the forearm. It separates the median cubital vein from the brachial artery, and may be pierced by the perforating vein of this region. The sharp concave upper border of the aponeurosis is easily felt when the supinated forearm is flexed against resistance.

3. The tendon of insertion of the biceps is twisted in such a way that its anterior part is formed by the short head, and the posterior part by the long head.

Additional Points about the Brachialis

Variations
(a) The muscle may be divided into two or more parts.
(b) It may fuse with the brachioradialis.
(c) It may send a tendinous slip to the radius, or to the bicipital aponeurosis.

[MUSCULOCUTANEOUS NEKVE]>»*^jgh

The musculocutaneous nerve is the main nerve of the front of the arm, and continues below the elbow as the lateral cutaneous nerve of the forearm (Fig. 6.1). It is a branch of the lateral cord of the brachial plexus, arising at the lower border of the pectoralis minor (Fig. 4.7).

Surface Marking

Musculocutaneous nerve is marked by joining the following two points (Fig. 8.7).

(i) A point lateral to the axillary artery 3 cm above its termination, (ii) A point lateral to the tendon of the biceps brachii muscle 2 cm above the bend of the elbow. (Here it pierces the deep fascia and continues as the lateral cutaneous nerve of the forearm.)

![Fig. 8.7: Nerves in front of arm related to axillary and brachial arteries.](image)

Root Value

The root value of musculocutaneous nerve is ventral rami of C5-C7 segments of spinal cord.

Course and Relations

In the lower part of the axilla: It accompanies the third part of the axillary artery and has the following relations.

Anteriorly. Pectoralis major.
Posteriorly. Subscapularis.
Medially. Axillary artery and lateral root of the median nerve (Fig. 4.13).
Laterally. Coracobrachialis (Fig. 4.14).

Musculocutaneous nerve leaves the axilla, and enters the front of the arm by piercing the coracobrachialis (Fig. 8.8).
In the arm: It runs downward and laterally between the biceps and brachialis to reach the lateral side of the tendon of the biceps. It ends by piercing the fascia 2 cm above the bend of the forearm.

Branches and Distribution

Muscular: It supplies the following muscles of the front of the arm:

(i) Coracobrachialis
(ii) Biceps, long and short heads
(iii) Brachialis (Figs 8.8, 8.9).

Cutaneous: Through the lateral cutaneous nerve of the forearm it supplies the skin of the lateral side of the forearm from the elbow to the wrist.

Articular branches: These supply: (a) the elbow joint through its branch to the brachialis; and (b) the humerus through a separate branch which enters the bone along with its nutrient artery.

Communicating branches. The musculocutaneous nerve communicates with the neighbouring nerve, namely, the superficial branch of the radial nerve, the posterior cutaneous nerve of the forearm, and the palmar cutaneous branch of the median nerve.

Variations

(1) Instead of piercing the coracobrachialis muscle, the musculocutaneous nerve may pass behind it to reach the interval between the biceps and the brachialis.

(2) Temporarily, it may either give fibres to, or receive fibres from, the median nerve.

Dissection

Dissect the brachial artery as it lies on the medial side of the upper part of the arm medial to median nerve and lateral to ulnar nerve (Fig. 8.10). IntaB lower half of the upper arm, the brachial artery is seen lateral to the median nerve as it passes behind the biceps, the nerve to the brachialis; and a separate branch which enters the bone along with its nutrient artery.

The musculocutaneous nerve communicates with the surrounding nerve, namely, the superficial branch of the radial nerve, the posterior cutaneous nerve of the forearm, and the palmar cutaneous branch of the median nerve.

Brachial artery is the continuation of the axillary artery. It extends from the lower border of the teres major muscle to a point in front of the elbow, at the level of the neck of the radius, just medial to the tendon of the biceps brachii.

Surface Marking

The brachial artery is marked by joining the following two points.

(i) A point at the junction of the anterior one-third and posterior two-thirds of the lateral wall of the axilla at its lower limit. Here the axillary artery ends and the brachial artery begins (Fig. 8.7). The second point, at the level of the neck of the radius medial to the tendon of the biceps brachii. Thus the artery begins on the medial side of the upper part of the arm, and runs downwards and slightly laterally to end in front of the elbow. At its termination it bifurcates into the radial and ulnar arteries.
The Arm Course and Relation

1. It runs downwards and laterally, from the medial side of the arm to the front of the elbow.
2. It is superficial throughout its extent and is accompanied by two venae comitantes (Fig. 8.9).
3. Anteriorly, in the upper part of the arm it is related to the medial cutaneous nerve of the forearm; in the middle of the arm it is crossed by the median nerve from the lateral to the medial side; and in front of the elbow it is covered by the bicipital aponeurosis and the median cubital vein (Fig. 8.10).
4. Posteriorly, it is related to (i) the triceps, (ii) the radial nerve and the profunda brachii artery, (iii) insertion of the coracobrachialis, and (iv) the brachialis.
5. Medially, in the upper part it is related to the ulnar nerve and the basilic vein, and the lower part to the median nerve (Fig. 8.10).

branch arises in the lower part and takes part in the anastomosis round the elbow joint.

6. The artery ends by dividing into two terminal branches, the radial and ulnar arteries.

Variations

1. High division. Frequently the brachial artery divides at a higher level than usual into three trunks: radial, ulnar and common interosseous arteries. Most frequently the radial artery is given off at a higher level, and the continuation forms a common stem for the ulnar and common interosseous arter-
6. Laterally, it is related to the coracobrachialis, the biceps and the median nerve in its upper part; and to the tendon of the biceps at the elbow.

7. At the elbow, the structures from the lateral to the medial side are: (i) the radial nerve, (ii) the biceps tendon, (iii) the brachial artery, and (iv) the median nerve.

Branches

1. Unnamed muscular branches.
2. The profunda brachii artery arises just below the teres major and accompanies the radial nerve (Fig. 8.11).
3. The superior ulnar collateral branch arises in the upper part of the arm and accompanies the ulnar nerve.
4. A nutrient artery is given off to the humerus.
5. The inferior ulnar collateral (or supratrochlear)

Upper Limb

ies. Occasionally, the artery divides at a higher level into two trunks which reunite.
2. **Medial course.** Sometimes, the brachial artery descends towards the medial epicondyle. In such cases, it usually passes behind the supracondylar process of the humerus deep to a fibrous arch. Then it runs behind or through the pronator teres to the bend of the elbow.

**CLINICAL ANATOMY**

1. Brachial pulsations are felt or auscultated in front of the elbow just medial to the tendon of biceps while recording the blood pressure.
2. Although the brachial artery can be compressed anywhere along its course, it can be compressed most favourably in the middle of the arm, where it lies on the tendon of the coracobrachialis.

**ANASTOMOSIS AROUND THE ELBOW JOINT**

Anastomoses around the elbow joint links the brachial artery with the upper ends of the radial and ulnar arteries. It supplies the ligaments and bones of the joint. The anastomosis can be subdivided into the following parts.

- *In front of the lateral epicondyle* of the humerus, the anterior descending (radial collateral) branch of the profunda brachii anastomoses with the radial recurrent branch of the radial artery (Fig. 8.11).
- *Behind the lateral epicondyle* of the humerus, the posterior descending branch of the profunda brachii
artery (above) anastomoses with the interosseous recurrent branch of the posterior interosseous artery (below).

In front of the medial epicondyle of the humerus, the inferior ulnar collateral branch of the brachial! artery, and occasionally a branch from the superior* ulnar collateral artery (above), anastomoses with the I anterior ulnar recurrent branch of the ulnar artery (below).

Behind the medial epicondyle of the humerus, the superior ulnar collateral branch of the brachial I artery (above) anastomoses with the posterior ulnar recurrent branch of the ulnar artery, and a branch from the inferior ulnar collateral artery (from the medial side).

LARGE NERVES IN THE ARM

Median Nerve

Median nerve is closely related to the brachial artery throughout its course in the arm (Fig. 8.10). In the upper part, it is lateral to the artery; in the middle of the arm, it crosses the artery from lateral to the medial side; and remains on the medial side of the artery right up to the elbow.

In the arm, the median nerve gives off a branch to the pronator teres just above the elbow and vascular branches to the brachial artery. An articular branch to the elbow joint arises at, or just below, the elbow (For course in forearm and hand see Chapter 9.)

Ulnar Nerve

Ulnar nerve runs on the medial side of the brachial artery up to the level of insertion of the coracobrachialis, where it pierces the medial intermuscular septum and enters the posterior compartment of the arm. It is accompanied by the superior ulnar collateral vessels. At the elbow, it passes behind the medial epicondyle where it can be palpated with a finger (Fig. 8.12). The ulnar nerve is palpated behind the medial epicondyle. Its course in forearm and hand has been discussed in Chapter 9.

Radial Nerve

At the beginning of the brachial artery, the radial nerve lies posterior to the artery. Soon the nerve leaves the artery by entering the radial (spiral) groove on the back of the arm where it is accompanied by the profunda brachii artery (Fig. 8.12). In the lower part of the arm, the nerve appears again on the front of the arm where it lies between the brachialis (medially and the brachioradialis and extensor carpi radialis longus (laterally). Its branches will be discussed with the back of the arm.
CUBITAL FOSSA

Cubital Fossa is a triangular hollow situated on the front of the elbow. (It is homologous with the popliteal fossa of the lower limb situated on the back of the knee.)

DISSECTION

Identify the structures (see text) present in the roof of a shallow cubital fossa located on the front of the elbow. Separate the lateral and medial boundaries formed respectively by the brachioradialis and pronator teres muscles. Clean the contents: (i) terminal part of brachial artery bifurcating into radial and ulnar arteries; (ii) median nerve on the medial side of brachial artery; (iii) the radial nerve on the lateral side of the brachial artery; (iv) the tendon of biceps brachii muscle between the artery and radial nerve.

Identify brachialis and supinator muscles, forming the floor of cubital fossa.

Boundaries

Laterally — medial border of the brachioradialis (Fig. 8.13).
Medially — lateral border of the pronator teres. — is directed upwards, and is represented by an imaginary line joining

Roof: The roof of the cubital fossa (Fig. 8.14) is formed by:
(a) Skin
(b) superficial fascia containing the median cubital vein, the lateral cutaneous nerve of the forearm and the medial cutaneous of the forearm
(c) deep fascia.

---

fig. 8.12: nerves related to posterior aspect of humerus.
fig. 8.13: boundaries of the left cubital fossa.
fig. 8.14: structures in the roof of the left cubital fossa.
(d) bicipital aponeurosis.

**Floor:** It is formed by: (i) the brachialis and (ii) the supinator muscles (Fig. 8.15).

**Contents**

The fossa is actually very narrow. The contents described are seen after retracting the boundaries. From medial to the lateral side, the contents are:

1. **The median nerve.** It gives branches to flexor carpi radialis, palmaris longus, flexor digitorum superficialis and leaves the fossa by passing between the two heads of pronator teres (Fig. 9.16).
2. The termination of the brachial artery, and the beginning of the radial and ulnar arteries lie in the fossa. The radial artery is smaller and more superficial than the ulnar artery. It gives off the radial recurrent branch. The ulnar artery goes deep and runs downwards and medially, being separated from the median nerve by the deep head of the pronator teres. It gives off the anterior ulnar recurrent, the posterior ulnar recurrent, and the common interosseous branches. The common interosseous branch divides into the anterior and posterior interosseous arteries, and latter gives off the interosseous recurrent branch.
3. **The tendon of the biceps, with the bicipital aponeurosis** (Fig. 8.16).
4. **The radial nerve** (accompanied by the radial collateral artery) appears in the gap between the brachialis (medially) and the brachioradialis and extensor carpi radialis longus laterally (Fig. 8.17). While running in the intermuscular gap, radial nerve supplies the three flanking muscles, and at the level of the lateral epicondyle it gives off the posterior interosseous nerve or deep branch of the radial nerve which leaves the fossa by piercing the supinator muscle (Fig. 8.18).

**CLINICAL ANATOMY**

The cubital region is important for the following reasons.

1. The median cubital vein is often the vein of choice for intravenous injections (see the superficial vein of the upper limb).
2. The blood pressure is universally recorded by auscultating the brachial artery in front of the elbow.
3. The anatomy of the cubital fossa is useful while dealing with the fracture around the elbow, like the supracondylar fracture of the humerus.

DISSECTION

Reflect the skin of back of arm to view the triceps brachii muscle. Define its attachments and separate the long head of the muscle from its lateral head. Radial nerve will be seen passing between the long head of triceps and medial border of the humerus. Note the continuity of radial nerve upto axilla. Carefully cut through the lateral head of triceps to expose radial nerve along with profunda brachii vessels. Note that the radial nerve lies in the radial groove, on the back of humerus, while passing between the lateral head of triceps above and its medial head below. In the lower part of arm, the radial nerve lies on the front of elbow just lateral to the brachialis, dividing into two terminal branches in the cubital fossa. The ulnar nerve (which was seen in the anterior compartment of arm till its middle) pierces the medial intermuscular septum with its accompanying vessels, reaches the back of elbow and may easily be palpated on the back of medial epicondyle of humerus.

TRICEPS BRACHII MUSCLE

Origin

Triceps brachii muscle arises by the following three heads (Fig. 8.19).

1. The long head arises from the infraglenoid tubercle of the scapula; it is the longest of the three heads.
2. The lateral heads arises from an oblique ridge on the upper part of the posterior surface of the humerus, corresponding to the lateral lip of the radial (spiral) groove.
3. The medial head arises from a large triangular area on the posterior surface of the humerus below the radial groove, as well as from the medial and
lateral intermuscular septa. At the level of the radial groove, the medial head is medial to the lateral head.

**Insertion**

The long and lateral heads converge and fuse to form a superficial flattened tendon which covers the medial head and inserted into the the posterior part of the superior surface of the olecranon process. The medial head is inserted partly into the superficial tendon, and partly into the olecranon. Although the medial head is separated from the capsule of the elbow joint by a small bursa, a few of its fibres are inserted into this part of the capsule: this prevents nipping of the capsule during extension of the arm. (These fibres are referred to as the *articularis cubiti*, or as the *subanconeus*.)

**Nerve Supply**

Each head receives a separate branch from the the radial nerve (C7, C8). The branches arise in the axilla and in the radial groove.

**Actions**

The triceps is a powerful active extensor of the elbow. The long head supports the head of the humerus in the abducted position of the arm. Gravity extends the elbow passively.

Electromyography has shown that the medial head of the triceps is active in all forms of extension, and the actions of the long and lateral heads are minimal, except when acting against resistance. Triceps is tested against resistance as shown in Fig. 8.20.

---

**RADIAL NERVE**

Radial nerve is the largest branch of the posterior cord of the brachial plexus with a root value of C5-C8, T1 (Fig. 4.7).

**Surface Marking**

*In the Arm:* It is marked by joining the following 3 points (Fig. 8.21):

(i) The first point is at the junction of the anterior one-third and posterior two-thirds of the lateral wall of the axilla at its lower limit, (ii) The second point is at the junction of the upper one-third and lower two-thirds a line joining the lateral epicondyle with the insertion of the deltoid, (iii) The third point is on the front of the elbow at the level of the lateral epicondyle 1 cm lateral to the tendon of the biceps brachii. The first and second points are joined across the back of the arm to mark the oblique course of the radial nerve in the radial (spiral) groove (posterior)

---

**Fig. 8.20:** Testing triceps against resistance.

**Fig. 8.21:** Surface projection of axillary, radial and posterior interosseous nerves (posterior view of limb).
Impartment). The second and third points are joined in the front of the arm to mark the vertical course of the nerve in the anterior compartment.

**Course and Relations**

A. In the lower part of the axilla, radial nerve passes downwards and has the following relations.

**Anteriorly** Third part of the axillary artery (Fig. 4.13).

**Posteriorly** Subscapularis, latissimus dorsi and teres major.

**Laterally** Axillary nerve and coracobrachialis.

**Medially** Axillary vein (Fig. 4.14).

B. In the upper part of the arm, it continues behind the brachial artery, and passes posterolaterally (with the profunda brachii vessels) through the lower triangular space, below the teres major, and between the long head of the triceps and the humerus. It then enters the radial groove with the profunda vessels (Figs 7.10, 7.11).

C. In the radial groove, the nerve runs downwards and laterally between the lateral and medial heads of the triceps, in contact with the humerus (Fig. 8.22). At the lower end of the groove, 5 cm below the deltoid tuberosity, the nerve pierces the lateral intermuscular septum and passes into the anterior compartment of the arm (Fig. 8.23). The part of the nerve in the cubital fossa has been described earlier.

**Branches and Distribution**

Various branches of radial nerve are shown in Fig. 8.24.
Fig. 8.24: Distribution of axillary and radial nerves.

Muscular

(1) Before entering the spiral groove, radial nerve supplies the long and medial heads of the triceps. (2) In the spiral groove, it supplies the lateral and medial heads of the triceps and the anconeus. (3) Below the radial groove, on the front of the arm, it supplies the brachialis with proprioceptive fibres, the brachioradialis, and the extensor carpi, radialis longus.

Cutaneous Branches

(1) Above the radial groove, radial nerve gives off the posterior cutaneous nerve of the arm which supplies the skin on the back of the arm.

(2) In the radial groove, the radial nerve gives off the lower lateral cutaneous nerves of the arm and the posterior cutaneous nerve of the forearm.

Articular branches: The articular branches near the elbow supply it the elbow joint.

CLINICAL ANATOMY

The radial nerve is very commonly damaged in the region of the radial (spiral) groove. The common causes of injury are: (i) intramuscular injections in the arm (triceps), (ii) sleeping in an armchair with the limb hanging by the side of the chair (Saturday night palsy), or even the pressure by a crutch (crutch paralysis), and (iii) fractures of the shaft of the humerus. This results in the weakness or loss of power of extension at the wrist (wrist drop) and sensory loss over a narrow strip on the back of forearm, and on the lateral side of the dorsum of the hand.

The course of the radial nerve in the forearm and hand is described in Chapter 9.

PROFUNDA BRACHII ARTERY

Profunda brachii artery is a large branch, arising just below the teres major. It accompanies the radial nerve through the radial groove, and before piercing the lateral intermuscular septum it divides into the anterior and posterior descending branches which take part in the anastomosis around the elbow joint (Fig. 8.11).

Branches

1. The radial collateral (anterior descending) artery is one of the terminal branches, and represents the continuation of the profunda artery. It accompanies the radial nerve, and ends by anastomosing with the radial recurrent artery in front of the lateral epicondyle of the humerus (Figs 8.22, 8.23).

2. The middle collateral (posterior descending) artery is the largest terminal branch, which descends in the substance of the medial head of the triceps. It ends by anastomosing with the interosseous recurrent artery, behind the lateral epicondyle of the humerus. It usually gives a branch which accompanies the nerve to the anconeus.
3. The deltoïd (or ascending) branch ascends between the long and lateral heads of the triceps, and anastomoses with the descending branch of the posterior circumflex humeral artery.

4. The nutrient artery to the humerus is often present. It enters the bone in the radial groove just behind the deltoïd tuberosity. However, it may be remembered that the main artery to the humerus is a branch of the brachial artery.

Additional Reading

The Forearm and Hand

Forearm extends between the elbow and the wrist joints. Radius and ulna form its skeleton. These two bones articulate at both their ends to form superior and inferior radioulnar joints. Their shafts are kept at optimal distance by the interosseous membrane. Muscles accompanied by nerves and blood vessels are present both on the front and the back of the forearm. Hand is the most distal part of the upper limb, meant for carrying out diverse activities. Numerous muscles,
tendons, bursae, blood vessels and nerves are artistically placed and protected in this region.

**THE FRONT OF THE FOREARM**

The front of the forearm presents the following components for study.

**Components**

1. Eight muscles, five superficial and three deep.
2. Two arteries, radial and ulnar.
3. Three nerves, median, ulnar and radial. These structures can be better understood by reviewing the long bones of the upper limb and having an articulated hand by the side.

**SURFACE LANDMARKS OF FRONT AND SIDES OF FOREARM**

1. The epicondyles of the humerus have been examined. Note that medial epicondyle is more prominent than the lateral. The posterior surface of the medial epicondyle is crossed by the ulnar nerve which can be rolled under the palpating finger. Pressure on the nerve produces tingling sensations on the medial side of the hand (Fig. 8.1).
2. The tendon of the biceps brachii can be felt in front of the elbow. It can be made prominent by
flexing the elbow joint against resistance. Pulsations of the brachial artery can be felt just medial to the tendon.

1. The head of the radius can be palpated in a depression on the posterolateral aspect of the extended elbow, distal to the lateral epicondyle. Its rotation can be felt during pronation and supination of the forearm.

2. The styloid process of the radius project 1 cm lower than the styloid process of the ulna (Fig. 9.1). It can be felt in the upper part of the anatomical snuff box. Its tip is concealed by the tendons of the
abductor pollicis longus and the extensor pollicis brevis, which must be relaxed during palpation.

1. The head of the ulna forms a surface elevation on the medial part of the posterior surface of the wrist when the hand is pronated.

2. The styloid process of the ulna projects downwards from the posteromedial aspect of the lower end of the ulna. Its tip can be felt on the posteromedial aspect of the wrist, where it lies about 1 cm above the tip of the styloid process of the radius (Fig. 9.1).

3. The pisiform bone can be felt at the base of the hypothenar eminence (medially) where the tendon of the flexor carpi ulnaris terminates. It becomes visible and easily palpable at the medial end of the transverse crease (junction of forearm and hand) when the wrist is fully extended.

4. The hook of the hamate lies one finger breadth below the pisiform bone, in line with the ulnar border of the ring finger. It can be felt only on deep palpation through the hypothenar muscles.

5. The tubercle of the scaphoid lies beneath the lateral part of the distal transverse crease in an extended wrist. It can be felt at the base of the thenar eminence in a depression just lateral to the tendon of the flexor carpi radialis (Fig. 9.2).

1. The tubercle (crest) of the trapezium may be felt on deep palpation inferolateral to the tubercle of the scaphoid.

2. The brachioradialis becomes prominent along the lateral border of the forearm when the elbow is flexed against resistance in the midprone position of the hand.

3. The tendons of the flexor carpi radialis, palmaris longus, and flexor carpi ulnaris can be identified on the front of the wrist when the hand is flexed against resistance. The tendons lie in the order stated, from lateral to medial side.

The pulsation of the radial artery can be felt in front of the lower end of the radius just lateral to the tendon of the flexor carpi radialis.

2. The pulsations of the ulnar artery can be felt by careful palpation just lateral to the tendon of the flexor carpi ulnaris. Here the ulnar nerve lies medial to the artery.

3. The transverse creases in front of the wrist are important landmarks. The proximal transverse crease lies at the level of the wrist joint, and distal crease corresponds to the proximal border of the flexor retinaculum.

4. The median nerve is very superficial in position at and above the wrist. It lies along the lateromedial edge of the tendon of the palmaris longus at the middle of the wrist.

5. The anatomical snuff box is a depression which appears on the lateral side of the wrist when the thumb is extended. It is bounded anteriorly by the abductor pollicis longus and extensor pollicis brevis, and posteriorly by the extensor carpi ulnaris. Pulsations of the radial artery can be felt in the floor of the depression against the scaphoid and trapezium. The beginning of the cephalic vein can be seen in its roof. The styloid process of the radius can be felt in the upper part of the depression as already mentioned.

SUPERFICIAL MUSCLES OF THE FRONT OF THE FOREARM

The muscles of the front of the forearm may be divided into superficial and deep groups.

The skin of the forearm has already been reflected on each side. Cut through the superficial and deep fasciae to expose the superficial muscles of the forearm. Identify these five superficial muscles. These are from lateral to medial side, pronator teres getting inserted into middle of radius, flexor carpi radialis reaching till the wrist, palmaris longus continuing with palmar aponeurosis, flexor digitorum superficialis passing through the palm and most medially the flexor carpi ulnaris getting inserted into the pisiform bone (Fig. 9.3).

Deep muscles

Cut through the origin of superficial muscles of forearm at the level of medial epicondyle of humerus and reflect them distally. This will expose the three deep muscles, e.g. flexor pollicis longus, flexor digitorum profundus and pronator quadratus.
There are five muscles in the superficial group. These are the pronator teres, the flexor carpi radialis, the palmaris longus, the flexor carpi ulnaris, and the flexor digitorum superficialis (sublimus).

**Common Flexor Origin**

All the superficial flexors of the forearm have a common origin from the front of the medial epicondyle of the humerus. This is called the common flexor origin.

**Pronator Teres**

*Origin*

1. **Humeral head** from the medial epicondyle of the humerus—common flexor origin (Fig. 9.3).
2. **Ulnar head** or deep head from the medial margin of the coronoid process of the ulna.

*Insertion*

Middle one-third of the lateral surface of the shaft of the radius.

*Nerve Supply*

Median nerve.

*Action*

It is the main pronator of the forearm. It also flexes the elbow.

*Important Relations*

The median nerve passes between the two heads of the muscle. The ulnar artery is deep to both heads.

*Variations*

The ulnar head may be absent. Additional slips may be derived from the biceps, the brachialis, the medial intermuscular septum, or the supracondylar process of the humerus.

**Flexor Carpi Radialis**

*Origin*

From the medial epicondyle of the humerus (common flexor origin).

*Insertion*

Into palmar surface of the bases of the second and third metacarpal bones.

*Nerve Supply*

Median nerve.

*Important Relation*

In the lower part of the forearm, the radial artery lies between the tendons of the brachioradialis and the flexor carpi radialis.

*Variations*

Proximally the muscle may have additional slips, and distally additional insertions on the flexor retinaculum, trapezium, and the 4th metacarpal bone.

**Palmaris Longus**

*Origin*

Medial epicondyle of the humerus (common flexor origin).

*Insertion*

Distal half of flexor retinaculum and the apex of the palmar aponeurosis.
Nerve Supply
Median nerve.

Action
Palmaris longus flexes the wrist and makes the palmar aponeurosis tense.

Additional Points
(i) At the wrist, the tendon lies over the median nerve which projects on its lateral side, (ii) The tendon enters the hand by passing superficial to the flexor retinaculum.
(iii) The palmaris longus muscle is more important morphologically than functionally. It is a degenerating muscle as it has a short belly and a long tendon. It is absent in 10% subjects.
(iv) The palmar aponeurosis represents the distal part of the tendon of the palmaris longus, another evidence of retrogression of the muscle (cf. the plantaris in the leg).
(v) Variations in size, shape and attachments are common.

Flexor Carpi Ulnaris

Origin
1. Humeral head from the medial epicondyle of the humerus (common flexor origin).
2. Ulnar head from the medial margin of the olecranon and by an aponeurosis from the posterior border of the ulna. The ulnar nerve passes between the humeral and ulnar heads.

Insertion
The insertion is primarily into the pisiform bone, but the pull of the muscle is transmitted through the pisohamate and pisometacarpal ligaments to the hook of the hamate and the base of the 5th metacarpal bone (which represent the true insertion of the muscle). The pisiform bone may, therefore, be regarded as a sesamoid bone developed within the tendon of the muscle.

Nerve Supply: Ulnar nerve.

Actions
1. Flexion of the wrist (along with the flexor carpi radialis and the palmaris longus).
2. Adduction of the wrist (along with the extensor carpi ulnaris).
3. Fixes the pisiform bone during contraction of the hypothenar muscles.

Additional Points
1. The humeral and ulnar heads of the flexM carpi ulnaris are connected together by a tendinous arch. The ulnar nerve enters the forearm by passing deep to this arch, between the two heads of the muscle. The posterior ulnar recurrent artery passes upwards through the same gap.
2. Above the wrist, the ulnar nerve and vessels lie lateral to the tendon of the flexor carpi ulnaris.
3. The pisiform bone is a sesamoid bone in the tendon of this muscle.
4. Proximally, an additional slip from the corono-oid process may be present. Distally, additional attachments to the flexor retinaculum, and the 4th or 5th metacarpal bones may be observed.

Flexor Digitorum Superficialis (Sublimus)
The Flexor digitorum superficialis is a large muscle forming a middle stratum between the other four superficial flexors and the deep flexors in front of the forearm (Fig. 9.4).

Origin
1. Humeral-ulnar head from the medial epicondyle of the humerus, the ulnar collateral ligament, and; tubercle on the medial border of the coronoid process of ulna.
2. The radial head arises from the anterior border of the radius up to the insertion of the pronator teres.
3. Some fibres arise from fibrous arch passin from the ulna to the radius and connecting the tw heads. The median nerve and the ulnar artery pass deep to this arch.

Insertion
The muscle ends in four tendons, one each for the medial four digits. Opposite the proximal phalanx the tendon for each digit splits into medial an lateral slips which are inserted on the correspondir sides of the middle phalanx. At the wrist the foi tendons are arranged in two pairs, the superfici; pair for the middle and ring fingers, and the deep pa for the index and little fingers. The tendons lie medi; to the palmaris longus and lateral to the ulnJ vessels and nerve.

The tendons enter the hand by passing deep to the flexor retinaculum, enclosed within a common syi oval sheath, the ulnar bursa (Fig. 9.5).

Nerve Supply: Median nerve A

T\%sV

I New\&Supply: Median nerve A
**Fig. 9.4:** The flexor digitorum superficialis muscle and its relationship to the median nerve and to the radial and ulnar arteries.

**Actions**

The flexor digitorum superficialis is the main flexor of the proximal interphalangeal joints. Secondarily, it may also flex the metacarpophalangeal and wrist joints.

**Variations**

1. The radial head may be absent.
2. A substantial sff from trie deep strraex o/tfre muscle may act on the index finger.
3. The tendon' to the little finger may be replaced an additional slip from the ulna, the flexor etinaculum or the palmar aponeurosis.
Deep muscles of the front of the forearm are the flexor digitorum profundus, the flexor pollicis longus and the pronator quadratus and are described in Tables 9.1 and 9.2. Following are some other points of importance about these muscles.

Additional Points about the Flexor Digitorum Profundus

1. It is the most powerful, and most bulky, muscle of the forearm. It forms the muscular elevation seen and felt on the posterior surface of the forearm medial to the subcutaneous posterior border of the ulna (Figs 9.6, 9.7).

2. The main gripping power of the hand is provided by the flexor digitorum profundus.

3. The muscle may be joined by accessory slips from the radius (action on the index finger), from the flexor digitorum superficialis, or from the flexor pollicis longus, or from the coronoid process of the ulna.

Additional Points about the Flexor Pollicis Longus

1. The anterior interosseous nerve and vessels descend on the anterior surface of the interosseous membrane between the flexor digitorum profundus and the flexor pollicis longus.

2. The tendon passes deep to the flexor retinaculum and the head of the adductor pollicis, to enter the fibrous flexor sheath of the thumb (Fig. 9.8).

3. The muscle may be connected by slips with the flexor digitorum superficialis, the flexor digitorum

profundus, or the pronator teres. The interosseous portion, or the whole muscle, may be absent.

Synovial Sheaths of Flexor Tendons

(1) Common flexor synovial sheath (ulnar bursa). The long flexor tendons of the fingers (flexor digitorum superficialis and profundus), are enclosed in a common synovial sheath while passing deep to the flexor retinaculum (carpal tunnel). The sheath has a parietal layer lining the walls of the carpal tunnel, and a visceral layer closely applied to the tendons.

From the arrangement of the sheath it appears that the synovial sac has been invaginated by the tendons from its lateral side. The synovial sheath extends upwards for 5 or 7.5 cm into the forearm and downwards into the palm up to the middle of the shafts of the metacarpal bones. It is important to note that the lower medial end is continuous with the digital synovial sheath of the little finger.

Infection of the ulnar bursa is usually secondary to infection of the little finger. In turn this may spread to the forearm space of Parona. It results in
an hour-glass swelling called a compound palmar ganglion.

(2) The synovial sheath of the tendon of flexor pollicis longus (radial bursa). This sheath is usually separate but may communicate with the common sheath behind the retinaculum. Superiorly, it is coextensive with the common sheath and inferiorly it extends up to the distal phalanx of the thumb.

(3) The digital synovial sheaths. The sheaths en close the flexor tendons in the fingers and line the fibrous flexor sheaths. The digital sheath of the little finger is continuous with the ulnar bursa, and that of the thumb with the radial bursa. However, the digital sheaths of the index, middle and ring fingers are separate and independent (Fig. 9.9).
**Vincula Longa and Brevia**

The vincula longa and brevia are synovial folds, similar to the mesentery, which connect the tendons to the phalanges. They transmit vessels to the tendons (Fig. 9.10).

**Arteries on the Front of the Forearm**

The most conspicuous arteries of the forearm are the radial and ulnar arteries. However, they mainly
Radial Artery

**Surface Marking**

Radial artery is marked by joining the following two points (Fig. 9.11).

(i) A point in front of the elbow at the level of the neck of the radius medial to the tendon of the biceps brachii. (ii) The second point at the wrist between the anterior border of the radius laterally and the tendon of the flexor carpi radialis medially, where the radial pulse is commonly felt. Its course is curved with a gentle convexity to the lateral side.

Having dissected the superficial and deep group of muscles of the forearm, identify the terminal branches of the brachial artery, e.g. ulnar and radial arteries and their branches. Radial artery follows the direction of the brachial artery. Ulnar artery passes obliquely deep to heads of pronator teres and then runs vertically till the wrist. Carefully look for common interosseous branch of ulnar artery and its anterior and posterior branches.

**Course and Relations**

Radial artery is the smaller terminal branch of the brachial artery in the cubital fossa. It runs downwards to the wrist with a lateral convexity. It leaves the forearm by turning posteriorly and entering the anatomical snuff box. As compared to the ulnar artery, it is quite superficial throughout its whole course. Its distribution in the hand is described later. Its relations are as follows:

1. **Anteriorly**, it is overlapped by the brachioradialis in its upper part, but in the lower half it is covered only by skin, superficial and deep fascia.
2. **Posteriorly**, the following structures form the bed of the radial artery (Fig. 9.12):
   (i) Biceps tendon
   (ii) Supinator
   (iii) Insertion of pronator teres (iv) Radial origin of the flexor digitorum superficialis

Supply the hand through the deep and superficial palmar arches. The arterial supply of the forearm is chiefly derived from the common interosseous branch of the ulnar artery, which divides into anterior and posterior interosseous arteries. The posterior interosseous artery is reinforced in the upper part and replaced in the lower part by the anterior interosseous artery.
ing with the palmar carpal branch of the ulnar artery, in front of the middle of the recurrent branch of the deep palmar arch, to form a cruciform anastomosis. The palmar carpal arch supplies bones and joints at the wrist.

4. The superficial palmar branch arises just before the radial artery leaves the forearm (by winding backwards). The branch passes through (occasionally over) the thenar muscles, and ends either by supplying these muscles, or by joining the terminal part of the ulnar artery to complete the superficial palmar arch.

**Variations**

1. **Higher origin.** In these cases, the radial artery arises more often from the axillary or upper part of the brachial artery, than from the lower part of the brachial artery.
2. **Superficial course.** In the forearm, the radial artery may lie in the superficial fascia. On turning round the wrist, it may pass superficial to the extensor tendons of the thumb.

**CLINICAL ANATOMY**

The radial artery is used for feeling the (arterial) pulse at the wrist. The pulsation can be felt well in this situation because of the presence of the flat radius behind the artery.

**Branches in the Forearm**

1. The radial recurrent artery arises just below the elbow, runs upwards deep to the brachioradialis, and ends by anastomosing with the radial collateral artery, in front of the lateral epicondyle of the humerus (Fig. 8.11).
2. **Muscular branches** are given to the lateral muscles of the forearm.
3. The palmar carpal branch arises near the lower border of the pronator quadratus, runs medially deep to the flexor tendons, and ends by anastomos-

**Ulnar Artery**

**Surface Marking**

The ulnar artery (Fig. 9.11) is marked by joining the following three points.

1. **Medially,** there is a point in front of the elbow at the level of the neck of the radius medial to the tendon of the biceps brachii.
2. **Laterally,** there is a second point at the junction of the upper one-third and lower two-thirds of the medial border of the arm, lateral to the ulnar nerve.
3. **[Specified third point.]**

Thus the course of the ulnar artery is oblique in the upper one-third, and vertical in its lower two-thirds. The ulnar nerve lies just medial to the ulnar artery in the lower two-thirds of its course. The ulnar artery continues in the palm as the superficial palmar arch.

**Course and Relations**

Ulnar artery is the larger terminal branch of the brachial artery, and begins in the cubital fossa (Fig. 9.13). The artery runs obliquely downwards and medially in the upper one-third of the forearm; but in the lower two-thirds of the forearm its course is vertical (Fig. 9.11). It enters the palm by passing...
superficial to the flexor retinaculum (Figs 9.4, 9.5). Its distribution in the hand is described later. Its relations are as follows.

1. **Anteriorly**, in its upper half, the artery is deep and is covered by: (i) the pronator teres (with the median nerve), (ii) the flexor carpi radialis, (iii) the palmaris longus, (iv) the flexor digitorum superficialis, and (v) the flexor carpi ulnaris. The lower half of the artery is superficial and is covered only by skin, superficial and deep fascia, and by the palmar cutaneous branch of the ulnar nerve (Figs 9.7, 9.8).

2. **Posteriorly**, the origin of the artery lies on the brachialis. In the rest of its course, the artery lies on the flexor digitorum profundus (Fig. 9.7).

3. **Medially**, it is related to the ulnar nerve, and to the flexor carpi ulnaris.

4. **Laterally**, it is related to the flexor digitorum superficialis (Fig. 9.4).

5. The artery is accompanied by two venae comitantes.

**Branches**

1. The **anterior and posterior ulnar recurrent arteries** anastomose around the elbow. The smaller anterior ulnar recurrent artery arises just below the elbow, runs upwards deep to the pronator teres, and ends by anastomosing with the inferior ulnar collateral artery in front of the medial epicondyle. The larger posterior ulnar recurrent artery arises lower than the anterior, runs backwards and upwards deep to the flexor digitorum superficialis, and between the heads of the flexor carpi ulnaris, and ends by anastomosing with the two ulnar collateral arteries behind the medial epicondyle (Fig. 8.11).

2. The **common interosseous artery** (about 1 cm long) arises just below the radial tuberosity. It passes backwards to reach the upper border of the interosseous membrane, and ends by dividing into the anterior and posterior interosseous arteries.

   **The anterior interosseous artery** is the deepest artery on the front of the forearm. It accompanies the anterior interosseous nerve. It descends on the surface of the interosseous membrane between the anterior interosseous nerve and the flexor pollicis longus (Fig. 9.7). It pierces the interosseous membrane at the upper border of the pronator quadratus to enter the extensor compartment (peroneal artery in the leg).

   The artery gives muscular branches to the deep muscles of the front of the forearm, nutrient branches to the radius and ulna, reinforcing branches to the extensor compartment, a descending branch to the anterior carpal arch, and a median artery which accompanies the median nerve.

   Near its origin, the **posterior interosseous artery** gives off the interosseous recurrent artery which runs upwards, and ends by anastomosing with middle collateral artery behind the lateral epicondyle.

1. **Muscular branches** supply the medial muscles of the forearm.

2. **Palmar and dorsal carpal** branches take part in the anastomosis round the wrist joint. The palmar carpal branch helps to form the palmar carpal arch.

   The dorsal carpal branch arises just above the pisiform bone, winds backwards deep to the tendons, and ends in the dorsal carpal arch. This arch is formed medially by the dorsal carpal branch of the ulnar artery, and laterally by the dorsal carpal branch of the radial artery. Superiorly, the arch is joined by the anterior and posterior interosseous arteries. Inferiorly, the arch supplies three slender dorsal metacarpal arteries.

**Variations**

**Higher origin and superficial course.** When the origin of the ulnar artery is high the artery arises more often from the brachial artery (than from the axillary artery). In such cases, the artery passes superficial to the forearm flexors either deep or superficial to the deep fascia; and the brachial artery becomes continuous with the common interosseous artery.
Near its origin the anterior interosseous artery gives off the median artery which accompanies and supplies the median nerve. The median artery may arise from the common interosseous artery. Sometimes this artery is large and reaches the palm.

NERVES OF THE FRONT OF THE FOREARM

Nerves of the front of the forearm are the median, ulnar and radial nerves. The radial and ulnar nerves ran along the margins of the forearm, and are never crossed by the corresponding vessels which gradually approach them. The ulnar artery, while approaching the ulnar nerve, gets crossed by the median nerve.

DISSECTION

Median nerve is the chief nerve of the forearm. It enters the forearm by passing between two heads of pronator teres muscle. Its anterior interosseous branch is given off as it is leaving the cubital fossa. Identify median nerve stuck to the fascia on the deep surface of flexor digitorum superficialis muscle. In the distal part it lies lateral to the above mentioned muscle (Fig. 9.4). Dissect the anterior interosseous nerve as it lies on the interosseous membrane between flexor pollicis longus and flexor digitorum profundus muscles (Fig. 9.7).

Identify the ulnar nerve situated behind the medial epicondyle. Trace it vertically down till the flexor retinaculum (Fig. 9.14).

Trace the radial nerve and its two branches in the lateral part of the cubital fossa. Its deep branch is muscular and superficial branch is cutaneous (Fig. 9.14).

Course and Relations

1. In the cubital fossa, median nerve lies medial to the brachial artery, behind the bicipital aponeurosis, and in front of the brachialis (Fig. 8.16).
2. The median nerve enters the forearm by passing between the two heads of the pronator teres. Here it crosses the ulnar artery from which it is separated by the deep head of the pronator teres (Figs 9.15, 8.16).
3. Along with the ulnar artery, the median nerve passes beneath the fibrous arch of the flexor digitorum

Median Nerve

Median nerve is the main nerve of the front of the forearm. It also supplies the muscles of thenar eminence.

Surface Marking

In the arm: Mark the brachial artery. The nerve is then marked lateral to the artery in the upper half, and medial to the artery in the lower half of the arm. The nerve crosses the artery anteriorly in the middle of the arm (Fig. 8.7).

In the forearm: It is marked by joining the following two points:

(i) A point medial to the brachial artery at the bend of the elbow (Fig. 9.14). (ii) A point in front of the wrist, over the tendon of the palmaris longus (or 1 cm medial to the tendon of the flexor carpi radialis).
superficialis, and runs deep to this muscle on the surface of the flexor digitorum profundus. It is accompanied by the median artery, a branch of the anterior interosseous artery. About 5 cm above the flexor retinaculum (wrist), it becomes superficial and lies between the tendons of the flexor carpi radialis (laterally) and the flexor digitorum superficialis (medially). It is overlapped by the tendon of the palmaris longus (Figs 9.4, 9.5).

4. The median nerve enters the palm by passing deep to the flexor retinaculum through the carpal tunnel (Fig. 9.5).

Branches and Distribution in the Forearm

1. Muscular branches are given off in the cubital fossa to flexor carpi radialis, palmaris longus and flexor digitorum superficialis.
2. The anterior interosseous branch is given off in the upper part of the forearm. It supplies the flexor pollicis longus, the lateral half of the flexor digitorum profundus (giving rise to tendons for the index and middle fingers) and the pronator quadratus. The nerve also supplies the distal radioulnar and wrist joints (Fig. 9.16).
3. The palmar cutaneous branch arises a short distance above the flexor retinaculum and supplies the skin over the thenar eminence and the central part of the palm.
4. Articular branches are given to the elbow joint and to the proximal radioulnar joint.
5. Vascular branches supply the radial and ulnar arteries.
6. A communicating branch is given to the ulnar nerve.

CLINICAL ANATOMY

1. The median nerve controls coarse movements of the hand, as it supplies most of the long muscles of the front of the forearm. It is, therefore, called the 'labourer's nerve'.
2. When the median nerve is injured above the level of the elbow, as might happen in supracondylar fracture of the humerus, the following features are seen.
   (a) The flexor pollicis longus is paralyzed. The patient is unable to bend the terminal phalanx of the thumb when the proximal phalanx is held firmly by the clinician (to eliminate the action of the short flexors). Similarly, the terminal phalanges of the index and middle fingers can be tested.
   (b) The forearm is kept in a supine position due to paralysis of the pronators.

(a) The hand is adducted due to paralysis of the flexor carpi radialis, and flexion at the wrist is weak.
(b) Flexion at the interphalangeal joints of the index and middle fingers is lost so that the index and to a lesser extent the middle fingers tend to remain straight while making a fist.
(c) Ape thumb deformity is present due to paralysis of the thenar muscles.
(d) The area of sensory loss in the hand is much less than the area of distribution.
(e) Vasomotor and trophic changes: The skin on lateral three and a half digits is warm, dry and scaly. The nails get cracked easily.

/3. Injury to the median nerve at the wrist is much more common than at the elbow. This is due to the superficial position of the nerve at this site. It produces.
1. Ape thumb deformity where the thenar muscles are wasted, and the thumb is adducted and laterally rotated.
2. Opposition of the thumb is totally lost.
3. Paralysis of the first and second lumbricals makes the index and middle fingers lag behind in slowly making a fist. The sensory loss, vasomotor and trophic changes are similar to that seen in lesions of the nerve at the elbow.

The distribution of the median nerve in the hand, is described later in this chapter.

Ulnar Nerve

Surface Marking

Ulnar nerve is marked in the arm (Fig. 9.14) by joining the following points.

(i) A point at the junction of the anterior one-third and posterior two-thirds of the lateral wall of the axilla at its lower limit, i.e. the lower border of the teres major muscle.
(ii) The second point at the middle of the medial border of the arm (Fig. 8.7).
(iii) The third point behind the base of the medial epicondyle of the humerus.

Ulnar nerve is marked in the forearm by joining the following two points.

(i) A point on the back of the base of the medial epicondyle of the humerus.
(ii) The second point lateral to the pisiform bone.

In the lower two-thirds of the forearm, the ulnar nerve lies medial to the ulnar artery.
Course and Relations

1. At the elbow, the ulnar nerve lies behind the medial epicondyle of the humerus. It enters the forearm by passing between the two heads of the flexor carpi ulnaris (Fig. 9.13).

2. In the forearm, the ulnar nerve runs between the flexor digitorum profundus and the flexor digitorum superficialis laterally. It enters the palm by passing superficial to the flexor retinaculum lateral to the pisiform bone.

3. At the wrist, the ulnar neurovascular bundle lies between the flexor carpi ulnaris and the flexor digitorum superficialis. The bundle enters the palm by passing superficial to the flexor retinaculum, lateral to the pisiform bone (Fig. 9.5).

Branches

(i) Muscular, to the flexor carpi ulnaris and the medial half of the flexor digitorum profundus.
(ii) Palmar and dorsal cutaneous branches. The palmar cutaneous nerve arises in the middle of the forearm and supplies the skin over the hypothenar eminence.

The dorsal branch arises 7.5 cm above the wrist, winds backwards and supplies the proximal part of the ulnar 2V0. fingers and the adjoining area of the dorsum of the hand.

(iii) Articular branches are given off to the elbow joint.

CLINICAL ANATOMY

1. The ulnar nerve is also known as the 'musician's nerve' because it controls fine movements of the fingers. Its details will be considered in the later part of this chapter.

2. The ulnar nerve is commonly injured at the elbow, behind the medial epicondyle; and at the wrist in front of the flexor retinaculum. *When the nerve is injured a t the elbow the flexor carpi ulnaris and the medial half of the flexor digitorum profundus are paralyzed. Due to this paralysis the medial border of the forearm becomes flattened. An attempt to produce flexion at the wrist result in abduction of the hand. The tendon of the flexor carpi ulnaris does not tighten on making a fist. Flexion of the terminal phalanges of the ring and little fingers is lost. Effects of paralysis on the hand (claw hand) will be considered later.*

Radial Nerve

Surface Marking

Radial nerve is marked by joining the following three points.

(i) A point 1 cm lateral to the biceps tendon at the level of the lateral epicondyle (Fig. 9.14). (ii) The second point at the junction of the upper two-thirds and lower one-third of the lateral border of the forearm just lateral to the radial artery, (iii) The third point at the anatomical snuff box. The nerve is vertical in its course between points one and two. At the second point it inclines backwards to reach the snuff box.

The nerve is closely related to the lateral side of the radial artery only in the middle one-third of the forearm (Fig. 9.13).

Course and Relations

1. The radial nerve divides into its two terminal branches in the cubital fossa at the level of the lateral epicondyle of the humerus (Fig. 8.16). The deep ter-
minal branch (posterior interosseous) soon enters the back of the forearm by passing through the supinator muscle. The superficial terminal branch (the main continuation of the nerve) runs down in front of the forearm.

2. The superficial terminal branch of the radial nerve is closely related to the radial artery only in the middle one-third of the forearm. In the upper one-third, it is widely separated from the artery, and in the lower one-third it passes backwards under the tendon of the brachioradialis. The superficial terminal branch is purely cutaneous and is distributed to the lateral half of the dorsum of the hand, and to the proximal parts of the dorsal surfaces of the thumb, the index finger, and lateral half of the middle finger. Injury to this branch results in small area of sensory loss over the root of the thumb.

THE PALMAR ASPECT OF THE WRIST AND HAND

The human hand is designed: (i) for grasping, (ii) for precise movements, and (iii) for serving as a tactile organ.

The skin of the palm is: (i) thick for protection of underlying tissues, (ii) immobile because of its firm attachment to the underlying palmar aponeurosis, and (iii) creased. All of these characters increase the efficiency of the grip.

The skin is supplied by spinal nerves C6, C7, C8 (Fig. 6.1) through the median and ulnar nerve.

The superficial fascia of the palm is made up of dense fibrous bands which bind the skin to the deep fascia (palmar aponeurosis) and divide the subcutaneous fat into small tight compartments which serve as water-cushions during firm gripping. The fascia contains a subcutaneous muscle, the palmaris brevis, which helps in improving the grip by steadying the skin on the ulnar side of the hand. The superficial metacarpal ligament which stretches across the roots of the fingers over the digital vessels and nerves, is a part of this fascia.

The deep fascia is specialized to form: (i) the flexor retinaculum at the wrist, (ii) the palmar aponeurosis in the palm, and (iii) the fibrous flexor sheaths in the fingers. All three form a continuous structure which holds the tendons in position and thus increases the efficiency of the grip.

Flexor Retinaculum

Flexor retinaculum is a strong fibrous band which bridges the anterior concavity of the carpus and converts it into a tunnel, the carpal tunnel.

DISSECTION

1. A horizontal incision at the distal crease of front of the wrist has already been made.
2. Make a vertical incision from the centre of the above incision through the palm to the centre of the middle finger (Fig. 9.17).
3. Give one horizontal incision along the distal palmar crease.
4. Give an oblique incision starting 3 cm distal to incision no. 2 and extend it till the tip of the distal phalanx of the thumb.

Thus the skin of the palm gets divided into 3 areas. Reflect the skin of lateral and medial flaps on their respective sides. The skin of the intermediate flap is reflected distally towards the distal palmar crease. Further the skin of middle finger is to be reflected on either side.

Superficial fascia and deep fascia

Remove the superficial fascia to clean the underlying deep fascia. Deep fascia is modified to form the flexor retinaculum at wrist, palmar aponeurosis in the palm, and fibrous flexor sheaths in the digits (Fig. 9.18). Identify the structures on its superficial surface. Divide the flexor retinaculum between the thenar and hypothenar eminences, carefully preserving the underlying median nerve and long flexor tendons. Identify long flexor tendons enveloped in their synovial sheaths including the digital synovial sheaths.

Surface Marking

Flexor retinaculum is marked by joining the following four points:
(i) Pisiform bone
(ii) Tubercle of the scaphoid bone

Fig. 9.17: Incisions of palm and digit.
The upper border is obtained by joining the first and second points, and the lower border by joining the third and fourth points (Fig. 9.18). The upper border is concave upwards, and the lower border is concave downwards.

**Attachments**

Medially, to (i) the pisiform bone, and (ii) to the hook of the hamate. Laterally, to (i) the tubercle of the scaphoid, and (ii) the crest of the trapezium.

On either side the retinaculum has a slip: (1) the lateral deep slip is attached to the medial lip of the groove on the trapezium which is thus converted into a tunnel for the tendon of the flexor carpi radialis; (2) the medial superficial slip (volar carpal ligament) is attached to the pisiform bone. The ulnar vessels and nerves pass deep to this slip.

**Relations**

The structures passing superficial to the flexor retinaculum are: (i) the tendon of the palmaris longus, (ii) the palmar cutaneous branch of the median nerve, (iii) the palmar cutaneous branch of the ulnar nerve, (iv) the ulnar vessels, and (v) the ulnar nerve. The flexor carpi ulnaris is partly inserted on the retinaculum, and the thenar and hypothenar muscles arise from it (Fig. 9.5).

The structures passing deep to the flexor retinaculum are: (i) the median nerve, (ii) the tendons of the flexor digitorum superficialis, (iii) the tendons of the flexor digitorum profundus, (iv) the tendons of the flexor pollicis longus, (v) the ulnar bursa, and (vi) the radial bursa. The tendon of the flexor carpi radialis lies between the retinaculum and its deep slip, in the groove on the trapezium.)

---

**CLINICAL ANATOMY**

**Carpal Tunnel Syndrome**

This syndrome consists of motor, sensory, vasomotor and trophic symptoms in the hand caused by compression of the median nerve in the carpal tunnel. Examination reveals wasting of thenar eminence (ape-like hand) hypoaesthesia to light touch on the palmar aspect of lateral 2>Vi digits. However, the skin over the thenar eminence is not affected as the branch of median nerve supplying it arises in the forearm.

*Motor changes:* Ape-like thumb deformity, loss of opposition of thumb, index and middle fingers lag behind while making the fist.

*Sensory changes:* Loss of sensations on lateral 3/2 digits including the nail beds and distal phalanges on dorsum of hand.

*Vasomotor changes:* The skin areas with sensory loss is warmer due to arteriolar dilatation; it is also drier due to absence of sweating due to loss of sympathetic supply.

*Trophic changes:* Long-standing cases of paralysis lead to dry and scaly skin. The nails crack easily with atrophy of the pulp of fingers.

It usually occurs in females between the age of 40 and 70. They complain of intermittent attacks of pain in the distribution of the median nerve on one or both
sides. The attacks frequently occur at night. Pain may be referred proximally to the forearm and arm.

**Palmar Aponeurosis**

This term is often used for the entire deep fascia of the palm. However, it is better to restrict this term to the central part of the deep fascia of the palm which covers the superficial palmar arch, the long flexor tendons, the terminal part of the median nerve, and the superficial branch of the ulnar nerve (Fig. 9.18).

**Features**

Palmar aponeurosis is triangular in shape. The *apex* which is proximal blends with the flexor retinaculum and is continuous with the tendon of the palmaris longus. The base is directed distally. It divides into four slips opposite the heads of the metacarpals of
the medial four digits. Each slip divides into two parts which are continuous with the fibrous flexor sheaths. Extensions pass to the deep transverse metacarpal ligament, the capsule of the metacarpophalangeal joints and the sides of the base of the proximal phalanx. The digital vessels and nerves, and the tendons of the lumbricals emerge through the intervals between the slips. From the lateral and medial margins of the palmar aponeurosis, the lateral and medial palmar septa pass backwards and divide the palm into compartments.

**Morphology**

Phylogenetically, the palmar aponeurosis represents the degenerated tendon of the palmaris longus.

**Functions**

Palmar aponeurosis fixes the skin of the palm and thus improves the grip. It also protects the underlying tendons, vessels and nerves.

**CLINICAL ANATOMY**

*Dupuytren’s Contracture*: This condition is due to inflammation involving the ulnar side of the palmar aponeurosis. There is thickening and contraction of the aponeurosis. As a result the proximal phalanx and later the middle phalanx become flexed and cannot be straightened. The terminal phalanx remains unaffected. The ring finger is most commonly involved.

**Fibrous Flexor Sheaths of the Fingers**

The fibrous flexor sheaths are made up of the deep fascia of the fingers. The fascia is thick and arched. It is attached to the sides of the phalanges and across the base of the distal phalanx. Proximally, it is continuous with a slip of the palmar aponeurosis.

In this way, a blind osseofascial tunnel is formed which contains the long flexor tendons enclosed in the digital synovial sheath (Fig. 9.19). The fibrous sheath is thick opposite the phalanges and thin opposite the joints to permit flexion.

The sheath holds the tendons in position during flexion of the digits.

**INTRINSIC MUSCLES OF THE HAND**

The intrinsic muscles of the hand serve the function of adjusting the hand during gripping and also for carrying out fine skilled movements. The origin and insertion of these muscles is within the territory of the hand.

There are 20 muscles in the hand, as follows.

1. (a) *Three muscles of thenar eminence*
   (i) Abductor pollicis brevis (Fig. 9.20). (ii) Flexor pollicis brevis. (iii) Opponens pollicis.
   (b) *One adductor of thumb* (i) Adductor pollicis.

2. *Four hypothenar muscles*
   (i) Palmaris brevis (Fig. 9.20). (ii) Abductor digiti minimi.
(iii) Flexor digiti minimi.
(iv) Opponens digitii minimi. I Muscles (ii)-(iv) are muscles of hypothenar eminence.

13. Four lumbricals. BV Four palmar interossei. B. Four dorsal interossei.

! These muscles are described below.

**DISSECTION**

Clean the thenar and hypothenar muscles. Carefully preserve the median nerve and superficial and deep branches of ulnar nerve which supply these muscles.

Abductor pollicis is the lateral muscle; flexor pollicis brevis is the medial one. Both these form the superficial lamina. The deeper lamina is constituted by opponens pollicis. Cut through the abductor pollicis to expose the opponens pollicis. These three muscles constitute the muscles of thenar eminence. Incise flexor pollicis brevis in its

(centre sod reflectits itw> parts This will reveal the tendon of flexor pollicis longus and adductor pollicis on a deeper plane. The muscles of thenar
eminence are supplied by thick recurrent branch of median nerve.

On the medial side of hand identify thin palmaris brevis muscle in the superficial fascia. It receives a twig from the superficial branch of ulnar nerve. Hypothenar eminence is comprised by abductor digiti minimi medially, flexor digiti minimi just lateral to it. Deep to both these lies opponens digiti minimi. Identify these three muscles and trace their nerve supply from deep branch of ulnar nerve.

Between the two eminences of the palm deep to palmar aponeurosis, identify the superficial palmar arch formed mainly by superficial branch of ulnar and superficial palmar branch of radial artery. Identify its common and proper digital branches. Clean, dissect and preserve the branches of the median nerve and superficial division of ulnar nerve in the palm lying between the superficial palmar arch and long flexor tendons (Fig. 9.21).

Lying on a deeper plane are the tendons of flexor digitorum superficialis muscle. Dissect the peculiar mode of its insertion in relation to that of tendon of flexor digitorum profundus.

Cut through the tendons of flexor digitorum superficialis 5 cm above the wrist. Divide both
ends of superficial palmar arch. Reflect them distally towards the metacarpophalangeal joints. Identify four tendons of flexor digitorum profundus diverging in the palm with four delicate muscles, the lumbricals arising from them. Dissect the nerve supply to these lumbricals. The first and second are supplied from median and third and fourth from the deep branch of ulnar nerve.

Divide the flexor digitorum profundus 5 cm above the wrist and reflect it towards the metacarpophalangeal joints. Trace one of its tendon to its insertion into the base of distal phalanx of one finger.

**Abductor Pollicis Brevis**

**Origin**
1. Tubercle of the scaphoid.
2. Crest of the trapezium.
3. Flexor retinaculum.

**Insertion**
1. Lateral side of the base of the proximal phalanx of the thumb.

**Nerve supply:** Median nerve (C8,T1), **Action:** Abduction of the thumb at the metacarpophalangeal and carpometacarpal joints. Abduction is associated with medial rotation.
The superficial head takes origin from
1. The crest of the trapezium.
2. The flexor retinaculum.
The deep head arises from the trapezoid and capitate bones.
Insertion: Lateral side of the base of the proximal phalanx.
Nerve Supply: It is supplied by the median nerve. The deep head may be supplied by the deep branch of the ulnar nerve. Action: Flexion of the thumb.

**Opponens Pollicis**

Origin
1. Crest of trapezium.
2. Flexor retinaculum.

Insertion: Lateral half of the palmar surface of the first metacarpal bone. Nerve Supply: Median nerve (C8, T1).
Action: Opposition of the thumb. This is a combination of flexion and medial rotation.

**Adductor Pollicis**

Origin
The muscle has two heads—oblique and transverse.
The oblique head arises from:
1. The capitate bone.
2. The base of the 2nd and 3rd metacarpal bones.
The transverse head arises from the palmar aspect of the third metacarpal bone.
Insertion: Medial side of the base of the proximal phalanx of the thumb.
Nerve Supply: Deep branch of ulnar nerve (C8, T1).
Action: The muscle adducts the thumb from the flexed or abducted position. The movement is forceful in gripping.

**Actions of Thenar Muscles**

In studying the actions of the thenar muscles, it must be remembered that the movements of the thumb take place in planes at right angles to those of the other digits because the thumb (first metacarpal) is rotated medially through 90 degrees. Flexion and extension of the thumb take place in the plane of the palm; and abduction and adduction at right angles to the plane of palm. Movement of the thumb across the palm to touch the other digits is known as
opposition. This movement is a combination of flexion and medial rotation.

**Palmaris Brevis**

This muscle is superficial and lies just under the skin.
*Origin:* From flexor retinaculum and palmar aponeurosis.
*Insertion:* Skin along medial border of the hand.
*Nerve Supply:* Ulnar nerve, superficial branch (C8, T1).
*Action:* Helps in gripping by making the hypothenar eminence more prominent, and by wrinkling the skin over it.

**Abductor Digiti Minimi**

*Origin:* This muscle arises from the pisiform bone. The origin extends on to the tendon of the flexor carpi ulnaris (proximally) and on to the pisohamate ligament (distally).
*Insertion:* Ulnar side of the base of the proximal phalanx of the little finger.
*Nerve Supply:* Deep branch of ulnar nerve (C8, T1).
*Action:* Abduction of little finger at the metacarpophalangeal joint.

**Flexor Digiti Minimi**

*Origin*
1. Hook of the hamate bone.
2. Flexor retinaculum.
*Insertion:* Ulnar side of the base of the proximal phalanx of the little finger.
*Nerve Supply:* Deep branch of the ulnar nerve (C8, T1).
*Action:* Flexion of the little finger at the metacarpophalangeal joint.

**Opponens Digiti Minimi**

*Origin*
1. Hook of the hamate.
2. Flexor retinaculum.
*Insertion:* Medial surface of the shaft of the fifth metacarpal bone.
*Nerve Supply:* Deep branch of ulnar nerve (C8, T1).
*Action:* Flexor of the fifth metacarpal and rotates it laterally (as making the palm hollow).

**Lumbral Muscles**

Lumbral muscles are four small muscles that take origin from the tendons of the flexor digitorum profundus. They are numbered from lateral to medial.
Origin: The first lumbrical arises from the radial side of the tendon for the index finger (Fig. 9.22). The second lumbrical arises from the radial side of the tendon for the middle finger. The third lumbrical arises from contiguous sides of the tendons for the middle and ring fingers. The fourth lumbrical arises from the contiguous sides of the tendons for the ring and little fingers.

Insertion: The tendons of the first, second, third and fourth lumbricals pass backwards on the radial side of the second, third, fourth and fifth metacarpophalangeal joints respectively. They are inserted into the dorsal digital expansions of the corresponding digits.

Nerve Supply
1. The first and second lumbricals by the median nerve (C8, T1).
2. The third and fourth lumbricals by the deep branch of the ulnar nerve (C8, T1).

Actions: The lumbrical muscles flex the metacarpophalangeal joints, and extend the interphalangeal joints of the digit into which they are inserted.

Deep to the lateral two tendons of flexor digitorum profundus muscle, note an obliquely placed muscle extending from two origins, i.e. from the shaft of the third metacarpal bone and the bases of 2nd and 3rd metacarpal bones and adjacent carpal bones to the base of proximal phalanx of the thumb. This is adductor pollicis. Reflect the adductor pollicis muscle from its origin towards its insertion. Identify the deeply placed interossei muscles. Identify the radial artery entering the palm between two heads of first dorsal interosseous muscle and then between two heads of adductor pollicis muscle turning medially to join the deep branch of ulnar artery to complete the deep palmar arch. Identify the deep branch of ulnar nerve lying in its concavity. Carefully preserve it, including its multiple branches. Deep branch of ulnar nerve ends by supplying the adductor pollicis muscle. It may supply deep head of flexor pollicis brevis also. Lastly, define four small palmar interossei and four relatively bigger dorsal interossei muscles (Figs 9.23, 9.24).

Palmar Interossei
Palmar interossei are four small muscles placed between the shafts of the metacarpal bones. They are numbered from lateral to medial side (Figs 9.24, 9.25).

Origin
1. First palmar interosseous muscle from the medial side of the base of the first metacarpal bone.
2. Second palmar interosseous muscle from the medial half of the palmar aspect of the shaft of the second metacarpal bone (Fig. 9.24).
Insertion
Each muscle is inserted into the dorsal digital expansion of one digit. It may also be attached to the base of the proximal phalanx of the same digit. The digits into which individual palmar interossei are inserted are as follows.
1. First muscle: Medial side of thumb.
2. Second muscle: Medial side of the index finger.
3. Third muscle: Lateral side of the fourth digit.
Note that the middle finger does not receive the insertion of any palmar interosseous muscle.

Nerve Supply
All palmar interossei are supplied by the deep branch of the ulnar nerve (C8, T1).

Actions
All palmar interossei adduct the digit to which they are attached towards the middle finger. In addition, they flex the digit at the metacarpophalangeal joint and extend it at the interphalangeal joints.

Dorsal Interossei
Like the palmar interossei the dorsal interossei are four small muscles placed between the metacarpal bones, and are numbered from lateral to medial side (Figs 9.25, 9.26).

Origin
1. First dorsal interosseous: Shafts of first and second metacarpals (Fig. 9.23).
3. Third dorsal interosseous: Shafts of third and fourth metacarpals.

Insertion
Each muscle is inserted into the dorsal digital expansion of the digit; and into the base of the proximal phalanx of that digit. The digits into which individual muscles are inserted are as follows:
1. First: Lateral side of index finger.
3. Third; Medial side of middle finger.
Note that the middle finger receives one ulrscsa' interosseous muscle on either side; and that the first and fifth digits do not receive any insertion.
**Nerve Supply**

All dorsal interossei are supplied by the deep branch of the ulnar nerve (C8, T1).

**Actions**

All dorsal interossei cause abduction of the digits away from the line of the middle finger. This movement occurs in the plane of palm (Fig. 9.27) in contrast to the movement of thumb where abduction occurs at right angles to the plane of palm (Fig. 9.28). Note that movement of the middle finger to either medial or lateral side constitutes abduction. Also note that the first and fifth digits do not require dorsal interossei as they have their own abductors. In addition (like the palmar interossei), the dorsal interossei flex the metacarpophalangeal joint of the digit concerned and extend the interphalangeal joints.

2. Testing the muscles:
   (i) The opponens pollicis is tested by asking the subject to touch the fingertips with the tip of the thumb.
   (ii) The dorsal interossei are tested by asking the subject to spread out the fingers against resistance.
   (iii) The palmar interossei and adductor pollicis are tested by placing a piece of paper between the fingers, between thumb and index finger and seeing how firmly it can be held (Fig. 9.29).
   (iv) The lumbricals and interossei are tested by asking the subject to flex the fingers at the metacarpophalangeal joints against resistance.

---

**Arteries of the Hand**

Arteries of the hand are the terminal parts of the ulnar and radial arteries. Branches of these arteries unite and form anastomotic channels called the superficial and deep palmar arches.

**Ulnar Artery**

The course of this artery in the forearm has been described earlier. It enters the palm by passing superficial to the flexor retinaculum. It ends by dividing into the superficial palmar branch, which is the main continuation of the artery, and the deep palmar branch. These branches take part in the formation of the superficial and deep palmar arches respectively.

**Superficial Palmar Arch**

The arch represents an important anastomosis between the ulnar and radial arteries along with the deep arch.

**Surface Marking**

Superficial palmar arch is formed by the direct continuation of the ulnar artery, and is marked as a curved line by joining these points:

---

![Fig. 9.27: The planes of movements of the fingers.](image)

![Fig. 9.28: The planes of movements of the thumb.](image)

**CLINICAL ANATOMY**

1. Paralysis of the intrinsic muscles of the hand produces *claw hand* in which there is hyper-extension at the metacarpophalangeal joints, and flexion at the interphalangeal joints. (The effect is opposite to the action of the lumbricals and interossei.)
(i) A point just lateral and distal to the pisiform bone
(ii) The second point on the hook of the hamate bone
(iii) The third point on the distal border of the thenar eminence in line with the cleft between the index and middle fingers.

The convexity of the arch is directed towards the fingers, and its most distal point is situated at the level of the distal border of the fully extended thumb.

The superficial palmar arch is formed as the direct continuation of the ulnar artery beyond the flexor retinaculum, i.e. by the superficial palmar branch. On the lateral side the arch is completed by one of the following branches of the radial artery: (i) superficial palmar branch, (ii) the radialis indicis, (iii) the princeps pollicis (Fig. 9.30).

**Branches**

Superficial palmar arch gives off four digital branches which supply the medial ?>Vi fingers. The lateral three digital branches are joined by the corresponding palmar metacarpal arteries from the deep palmar arch.

The deep branch of the ulnar artery arises in front of the flexor retinaculum immediately beyond the pisiform bone. Soon it passes between the flexor and abductor digiti minimi to join and complete the deep palmar arch.

**Radial Artery**

**Surface Marking**

Radial artery is marked by joining the following three points:

(i) A point at the wrist between the anterior border of the radius and the tendon of the flexor carpi radialis
(ii) A second point just below the tip of the styloid process of the radius
(iii) The third point at the proximal end of the first intermetacarpal space

---

**Fig. 9.30:** The superficial and deep palmar arches.
**Course and Relations**

In this part of its course, the radial artery runs obliquely downwards, and backwards deep to the tendons of the abductor pollicis longus, the extensor pollicis brevis, and the extensor pollicis longus, and superficial to the lateral ligament of the wrist joint. Thus it passes through the anatomical snuff box to reach the proximal end of the first interosseous space (Fig. 9.31). Further, it passes between the two heads of the first dorsal interosseous muscle and between the two heads of adductor pollicis to form the deep palmar arch in the palm.

*Fig. 9.31: Anatomical snuff box.*

The course of this artery in the forearm is described earlier.

1. It leaves the forearm by winding backwards *round the wrist*.
2. It passes through the anatomical snuff box where it lies deep to the tendons of the abductor pollicis longus, the extensor pollicis brevis and the extensor pollicis longus. It is also crossed by the digital branches of the radial nerve. The artery is superficial to the lateral ligament of the wrist joint, the scaphoid and the trapezium.
3. It reaches the proximal end of the first interosseous space and passes between the two heads of the first dorsal interosseous muscle to reach the palm.
4. In the palm, the radial artery runs medially. At first it lies deep to the oblique head of the adductor pollicis, and then passes between the two heads of this muscle. Therefore, it is known as the deep palmar arch (Fig. 9.30).
**Branches**

*Dorsum of hand:* On the dorsum of the hand the radial artery gives off:

1. A branch to the lateral side of the dorsum of the thumb.
2. The *first dorsal metacarpal artery.* This artery arises just before the radial artery passes into the interval between the two heads of the first dorsal interosseous muscle. It at once divides into two branches for the adjacent sides of the thumb and the index finger.

*Palm:* In the palm (deep to the oblique head of the adductor pollicis), the radial artery gives off:

1. The *princeps pollicis artery* which divides at the base of the proximal phalanx into two branches for the palmar surface of the thumb.
2. The *radialis indicis artery* descends between the first dorsal interosseous muscle and the transverse head of the adductor pollicis. It supplies the lateral side of the index finger. At the distal border of the transverse head of the adductor pollicis it anastomoses with the princeps pollicis artery, and gives a communicating branch to the superficial palmar arch.

The radialis indicis artery may arise from the princeps pollicis. Sometimes the princeps pollicis and the radialis indicis arteries arise by a common trunk called the first palmar metacarpal artery.

**Deep Palmar Arch**

**Surface Marking**

Deep palmar arch is formed as the direct continuation of the radial artery. It has a slight convexity towards the fingers. It is marked by a more or less horizontal line, 4 cm long, just distal to the *hook* of the hamate bone.

The deep palmar arch lies 1.2 cm proximal to the superficial palmar arch across the metacarpals, immediately distal to their bases. The deep branch of ulnar nerve lies in its concavity (Fig. 9.20).

This arterial arch provides a second channel connecting the radial and ulnar arteries in the palm (the first one being the superficial palmar arch already considered). It is situated deep to the long flexor tendons.

**Formation**

The deep palmar arch is formed mainly by the terminal part of the radial artery, and is completed medially at the base of the fifth metacarpal bone by the deep palmar branch of the ulnar artery.
Relations

The arch lies on the proximal parts of the shafts of the metacarpals, and on the interossei; under cover of the oblique head of the adductor pollicis, the flexor tendons of the fingers, and the lumbricals. The deep branch of the ulnar nerve lies within the concavity of the arch.

Branches

1. From its convexity, i.e. from its distal side, the arch gives off three palmar metacarpal arteries, which run distally in the 2nd, 3rd and 4th spaces, supply the medial four metacarpals, and terminate at the finger clefts by joining the common digital branches of the superficial palmar arch (Fig. 9.30).

2. Dorsally, the arch gives off three (proximal) perforating arteries which pass through the medial three interosseous spaces to anastomose with the dorsal metacarpal arteries. The digital perforating arteries connect the palmar digital branches of the superficial palmar arch with the dorsal metacarpal arteries.

3. Recurrent branch arises from the concavity of the arch and pass proximally to supply the carpal bones and joints, and end in the palmar carpal arch.

NERVES OF THE HAND

Ulnar Nerve

Ulnar nerve is the main nerve of the hand (like the lateral plantar nerve in the foot).

Course and Relations

1. The ulnar nerve enters the palm by passing superficial to the flexor retinaculum where it lies between the pisiform bone and the ulnar vessels. Here the nerve divides into its superficial and deep terminal branches (Figs 9.32, 9.33).

2. The superficial terminal branch supplies the palmaris brevis and divides into two digital branches for the medial fingers (Fig. 9.34).

3. The deep terminal branch accompanies the deep branch of the ulnar artery. It passes backwards between the abductor and flexor digiti minimi, and
then between the opponens digitii minimi and the fifth metacarpal bone, lying on the hook of the hamate. Finally, it turns laterally within the concavity of the deep palmar arch. It ends by supplying the adductor pollicis muscle (Fig. 9.33).

**Branches**

*From Superficial Terminal Branch*
1. Muscular branch: to palmaris brevis.
2. Cutaneous branches: two palmar digital nerves supply the medial one and a half fingers with their nail beds. The medial branch supplies the medial side of the little finger. The lateral branch is a common palmar digital nerve. It divides into two proper palmar digital nerves for the adjoining sides of the ring and little fingers. The common palmar digital nerve communicates with the median nerve.

From Deep Terminal Branch
1. Muscular branches: (a) at its origin the deepy branch supplies three muscles of hypothenar eminence, (b) as the nerve crosses the palm. It supplies the medial two lumbricals and eight interossei, (c) the deep branch terminates by supplying the adductor pollicis, and occasionally the deep head of the flexor pollicis brevis.
2. An articular branch supplies the wrist joint.

CLINICAL ANATOMY
1. The ulnar nerve is often called the 'musician's nerve' because it controls fine movements of the fingers through its extensive motor distribution to the short muscles of the hand.
2. The ulnar nerve is most commonly injured at two sites: behind the medial epicondyle of the
humerus, and at the wrist. At both sites, it is quite superficial and vulnerable to injury. An ulnar nerve lesion at the wrist produces 'ulnar claw-hand', involving mainly the ring and little fingers. True claw-hand, involving all the fingers is produced by a combined lesion of the ulnar and median nerve.

_Ulnar claw-hand_ is characterized by the following signs.

(a) Hyperextension at the metacarpophalangeal joints and flexion at the interphalangeal joints, involving the ring and little fingers—more than the index and middle fingers (Fig. 9.34). The little finger is held in abduction by extensor muscles. The intermetacarpal spaces are hollowed out due to wasting of the interosseous muscles. Claw-hand deformity is more obvious in wrist lesions as the profundus muscle is spared: this causes marked flexion of the terminal phalanges (action of paradox).

(b) Sensory loss is confined to the medial one-third of the palm and the medial one and a half fingers including their nail beds (Fig. 9.35).

(c) Vasomotor changes: The skin areas with sensory loss is warmer due to arteriolar dilatation; it is also drier due to absence of sweating due to loss of sympathetic supply.

(d) Trophic changes: Long-standing cases of paralysis lead to dry and scaly skin. The nails crack easily with atrophy of the pulp of fingers.

(e) The patient is unable to spread out the fingers due to paralysis of the dorsal interossei. The power of adduction of the thumb, and flexion of the ring and little fingers are lost. It should be noted that median nerve lesions are more disabling. In contrast, ulnar nerve lesions leave a relatively efficient hand.

^ Claw-hand can be produced by a number of lesions, including Klumpke's paralysis, lesion of the medial cord of the brachial plexus, lesion of the ulnar nerve, a combined lesion of the ulnar and median nerves. A similar deformity can also result from a late and severe Volkmann's ischaemic contracture, the end result of a neglected suppurative tenosynovitis of the ulnar bursa (Fig. 9.36). Ulnar nerve injury at the wrist can be excluded by Froment's sign, or the book test which tests the adductor pollicis muscle. When the patient is asked to grasp a book firmly between the thumb and other fingers of both the hands, the terminal phalanx of the thumb on the paralysed side becomes flexed at the interphalangeal joint (by the flexor pollicis longus which is supplied by the median nerve).
The median nerve is important because of its role in controlling the movements of the thumb which are crucial in the mechanism of gripping by the hand.

**Course and Relations**

1. The median nerve enters the palm by passing deep to the flexor retinaculum, where it lies in front of the ulnar bursa enclosing the flexor tendons, in the narrow space of the carpal tunnel. Immediately below the retinaculum the nerve divides into lateral and medial divisions (Fig. 2.31).

2. The lateral division gives off a muscular branch to the thenar muscles, and three digital branches for the lateral one and half digits including the thumb. The muscular branch curls upwards round the istal border of the retinaculum and supplies the thenar muscles. Out of the three digital branches, two supply the thumb and one the lateral side of the index finger. The digital branch to the index finger also supplies the first lumbrical (Fig. 9.33).

The medial division divides into two common digital branches for the second and third interdigital fss, supplying the adjoining sides of the index, middle and ring fingers. The lateral common digital branch also supplies the second lumbrical.
Distribution

In the hand, the median nerve supplies:
(a) Five muscles, namely the abductor pollicis brevis, the flexor pollicis brevis, the opponens pollicis and the first and second lumbrical muscles. 
(b) Palmar skin over the lateral three and a half digits with their nail beds.

CLINICAL ANATOMY

1. Median nerve injury at the wrist. This is a common occurrence and is characterized by the following signs.
   (a) The median nerve controls coarse movements of the hand and is the nerve of grasp. In all injuries of this nerve, at whatever level, the patient is unable to pick up a pin with the thumb and index finger. In fact, inability to oppose the thumb is the chief disability of median nerve lesions at the wrist.
   (b) Ape-like hand. Paralysis of the short muscles of the thumb, and the unopposed action of the extensor pollicis longus produces an ape-like hand. The thenar eminence is wasted and flattened. The thumb is adducted and laterally rotated so that the first metacarpal lies in the same plane as the other metacarpals.
   (c) Pen test for abductor pollicis brevis. Lay the hand flat on a table with the palm directed upwards. The patient is unable to touch with his thumb a pen held in front of the palm.
   (d) Sensory loss corresponds to distribution of the median nerve in the hand.

As already mentioned, median nerve lesions are more disabling than ulnar nerve lesions. This is largely due to the inability to oppose the thumb, so that the gripping action of the hand is totally lost.

1. Carpal tunnel syndrome. Involvement of the median nerve in carpal tunnel syndrome has been described earlier with flexor retinaculum.

2. If both median and ulnar nerves are paralysed, the result is complete claw-hand (Fig. 9.36).

Radial Nerve

The part of the radial nerve seen in the hand is a continuation of the superficial terminal branch. It reaches the dorsum of the hand (after winding round the lateral side of the radius) and divides into 4 or 5 dorsal digital branches which supply the skin of the digits as follows (Fig. 9.37).

1st: Lateral side of thumb
2nd: medial side of thumb
oru: laxeiai siue ui muex linger

4th: contiguous sides of index and middle fingers

5th: when present it supplies the contiguous sides of the middle and ring fingers

Note that skin over the dorsum of the distal phalanges, and part of the middle phalanges, is supplied by the median nerve (not radial). Sensory loss corresponds to the distribution of the nerve.

**THE SPACES OF THE HAND**

**Spaces of the Hand**

Having learnt the anatomy of the whole hand, the clinically significant spaces of the hand need to be understood and their boundaries to be identified from the following text.

The arrangement of fasciae and the fascial septa in the hand is such that many spaces are formed. These spaces are of surgical importance because they may become infected and distended with pus. The important spaces are as follows:

A. **Palmar Spaces**
   1. Pulp space of the fingers
   2. Midpalmar space
   3. Thenar space

B. **Dorsal Spaces**
   1. Dorsal subcutaneous space
   2. Dorsal subaponeurotic space

C. **The Forearm Space of Parona.**

**Pulp Space of the Fingers**

The tips of the fingers and thumb contain subcutaneous fat arranged in tight compartments formed by
fibrous septa which pass from the skin to the periostium of the terminal phalanx. Infection of this space is known as whitlow. The rising tension in the space gives rise to severe throbbing pain.

Infections in the pulp space (whitlow) can be drained by a lateral incision which opens all compartments and avoids damage to the tactile tissue in front of the finger.

If neglected, a whitlow may lead to necrosis of the distal four-fifths of the terminal phalanx due to occlusion of the vessels by the tension. The proximal one-fifth (epiphysis) escapes because its artery does not traverse the fibrous septa (Fig. 9.38).

Midpalmar Space

Midpalmar space is triangular space situated under the inner half of the hollow of the palm. Proximally, it extends up to the distal margin of the flexor retinaculum and communicates with the forearm space (Table 9.3). Distally, it extends up to the proximal transverse palmar crease and communicates with the fascial sheaths of the 3rd and 4th, occasionally 2nd lumbricals; occasionally 2nd lumbrical muscles (lumbrical canals) (Fig. 9.39). 

The space is bounded:

(a) Anteriorly by the palmar aponeurosis and the flexor tendons of the 3rd, 4th and 5th fingers:
   (i) the 2nd, 3rd and 4th lumbrical muscles; (ii) the superficial palmar arch; and (iii) the digital nerves and vessels of the medial three and a half fingers.

(a) Posteriorly, by the 3rd, 4th and 5th metacarpals. The fascia, covering the interossei of the 3rd and 4th spaces.

(b) Medially, by the medial palmar septum; and

(c) Laterally, by the intermediate palmar septum.

After the advent of antibiotics and advanced surgical techniques, the incidence of infection of the midpalmar space has been markedly reduced. Sometimes, however, infection of the space may result from tenosynovitis of the middle and ring fingers, or

(b) Posteriorly, by the fascia covering the transverse head of the adductor pollicis and the first dorsal interosseous muscle (Fig. 9.40);

(c) Medially, by the intermediate palmar septum; and

(d) Laterally, by the lateral palmar septum.

The thenar space may be infected by spread of any infection in the thumb or index finger. This results in marked swelling of the web of the thumb and thenar region. The thumb is held in an abducted position. The space can be drained by an incision in the first web posteriorly, or where the pus points.

**Dorsal Spaces**

The dorsal subcutaneous space lies immediately deep to the loose skin of the dorsum of the hand. The dorsal subtendinous space lies between the metacarpal bones and the extensor tendons which are united to one another by a thin aponeurosis.

Infection of the dorsal spaces is uncommon. However, sweating of the dorsum is very common and can be produced by almost every infection of the hand, especially in midpalmar space infections. Sometimes the dorsal spaces are infected after injury over the knuckles. In subcutaneous infections, the pus points through the skin, and can be drained at the pointing site. In subtendinous infections, the pus points either at the webs or at the borders of the hand, and can be drained accordingly.

**Forearm Space of Parona**

Forearm space of Parona is a rectangular space situated deep in the lower part of the forearm just above the wrist. It lies in front of the pronator quadratus, and deep to the long flexor tendons. Superiorly, the space extends up to the oblique origin of the flexor digitorum superficialis. Inferiorly, it extends up to the flexor retinaculum, and communicates with the midpalmar space; and possibly also with the thenar space. The proximal part of the flexor synovial sheaths protrudes into the forearm space.

The forearm space may be infected through infections in the related synovial sheaths, especially of the ulnar bursa. Pus points at the margins of the distal part of the forearm where it may be drained.

**SYNOVIAL SHEATHS**

Many of the tendons entering the hand are surrounded by synovial sheaths. The extent of these sheaths is of surgical importance as they can be infected (Fig. 9.9).

**Digital Synovial Sheaths**

The synovial sheaths of the 2nd, 3rd and 4th digits are independent and terminate proximally at the levels of the heads of the metacarpals. The synovial sheath of the little finger is continuous proximally with the ulnar bursa, and that of the thumb with the radial bursa. Therefore, infections of the little finger and thumb are more dangerous because they can spread in to the palm and even up to 2.5 cm above the wrist. In about 50% cases, the radial and ulnar bursae communicate with each other behind the flexor retinaculum.

Infections of the digital synovial sheaths are drained through two transverse incisions, one in the crease of the distal interphalangeal joint and the other in the distal palmar crease. This opens the sheath at either end.

**Ulnar Bursa**

Infection of this bursa is usually secondary to the infection of the little finger, and this in turn may spread to the forearm space of the Parona. It results in an hourglass swelling (so called because there is one swelling in the palm and another in the distal
part of the forearm, the two being joined by a constriction in the region of the flexor retinaculum).

The ulnar bursa is approached by an incision along the lateral margin of the hypothenar eminence.

Radial Bursa

Infection of the thumb may spread to the radial bursa and then to the ulnar bursa if these two communicate. It can be drained by an incision along the medial margin of the thenar eminence. The incision should be restricted proximally to avoid injury to the branch of the median nerve to the thenar muscles.

**Clinical Anatomy**

**Surgical Incisions of the Hand**

Incisions in the hand should be planned carefully to avoid contractures. In general, the incision should be transverse, parallel with the creases of the wrist, hand or fingers. They should never be at right angles to the creases. When necessary the transverse incision can be enlarged by a longitudinal extension at each end in opposite directions (Figs 9.41, 9.42).

A longitudinal incision in the fingers, palm, or wrist must be at the sides where the skin is least subjected to movements. Here the skin is thin and pliable and heals well in time.

**Optimum Position of the Hand**

When the hand requires prolonged immobilization, this must be done with the hand in optimum position to avoid any permanent joint stiffness. The optimum position is one in which the ligaments are at their maximum length. If the joints are immobilized for 3-6 weeks in any other position, the ligaments shorten and may never regain their normal length. In optimum position of the hand the wrist is dorsiflexed by 15 to 20 degrees, the metacarpophalangeal joints are flexed by 90 degrees, the interphalangeal joints are flexed by 5 degrees and the thumb is held in opposition.

**The Back of the Forearm and Hand**

This section deals mainly with the extensor retinaculum of the wrist, muscles of the back of the forearm, the deep terminal branch of the radial nerve, and the posterior interosseous artery.

1. The olecranon process of the ulna is the most prominent bony point on the back of a flexed elbow (Fig. 9.1). Normally, it forms a straight horizontal line with the two epicondyles of the humerus when the elbow is extended, and an equilateral triangle when the elbow is flexed to a right angle. The relative position of the three bony points is disturbed when the elbow is dislocated.

2. The head of the radius can be palpated in a depression on the posterolateral aspect of an extended elbow just below the lateral epicondyle of the humerus. Its rotation can be felt during pronation and supination of the forearm.

3. The posterior border of the ulna is subcutaneous in its entire length. It can be felt in a longitudinal
groove on the back of the forearm when the elbow is flexed and the hand is supinated. The border ends distally in the styloid process of the ulna. It separates the flexors from the extensors of the forearm. Being superficial, it allows the entire length of the ulna to be examined for fractures.

1. The head of the ulna forms a surface elevation on the posteromedial aspect of the wrist in a pronated forearm.

2. The styloid processes of the radius and ulna are important landmarks of the wrist. The styloid process of the radius can be felt in the upper part of the anatomical snuff box. It projects down 1 cm lower than the styloid process of the ulna. The latter descends from the posteromedial aspect of the ulnar head. The relative position of the two styloid processes is disturbed in fractures at the wrist, and is a clue to the proper realignment of fractured bones.

3. The dorsal tubercle of the radius (Lister's tubercle) can be palpated on the dorsal surface of the lower end of the radius in line with the cleft between the index and middle fingers. It is grooved on its medial side by the tendon of the extensor pollicis longus.

(7. The anatomical snuff box is a triangular depression on the lateral side of the wrist. It is seen best when the thumb is extended. It is bounded anteriorly by tendons of the abductor pollicis longus and extensor pollicis brevis, and posteriorly by the tendon of the extensor pollicis longus. It is limited above by the styloid process of the radius. The floor of the snuff box is formed by the scaphoid and the trapezium, and is crossed by the radial artery.) 8. The heads of the metacarpals form the knuckles.

Attachments

Laterally, to the lower part of the anterior border of the radius. Medially, to: (i) the styloid process of the ulna, (ii) the triquetral, and (iii) the pisiform bones.

Surface Marking

Extensor retinaculum is an oblique band directed downwards and medially, and is about 2 cm broad (vertically). Laterally, it is attached to the lower salient part of the anterior border of the radius, and medially to the medial side of the carpus (pisiform and triquetral bones) and to the styloid process of the ulna.

The deep fascia on the back of the wrist is thickened to form the extensor retinaculum which holds the extensor tendons in place. It is an oblique band, directed downwards and medially. It is about 2 cm broad vertically (Fig. 9.43J).

Make the incision in the centre of dorsum of hand. Reflect the skin of dorsum of hand till the respective borders. Reflect the skin of dorsum of middle finger on each side. Look for nerves on the back of forearm and hand. These are superficial branch of radial nerve and dorsal branch of ulnar nerve.

The dorsal venous network is the most prominent component of the superficial fascia of dor-
Compartments

be retinaculum sends down septa which are attached to the longitudinal ridges on the posterior surface of the lower end of radius. In this way, 6 fibrofascial compartments are formed on the back of the wrist. The structures passing through each compartment, from lateral to the medial side, are listed below.

Table 9.4: Structures in various compartments under extensor retinaculum

Each compartment is lined by a synovial sheath, which is reflected on to the contained tendons.

SUPERFICIAL MUSCLES OF THE BACK OF THE FOREARM

There are seven superficial muscles (Fig. 9.44) on the back of the forearm:

1. Anconeus
2. Brachioradialis
3. Extensor carpi radialis longus
4. Extensor carpi radialis brevis
5. Extensor digitorum
6. Extensor digiti minimi
7. Extensor carpi ulnaris.

All the seven muscles cross the elbow joint. Most of them take origin (entirely or in part) from the tip of the lateral epicondyle of the humerus.

This is the common extensor origin.

Sommon Extensor Origin

Anconeus

Origin: Posterior aspect of lateral epicondyle of the ulna.

Insertion: Lateral aspect of olecranon process of ulna.

2. Upper one-fourth of the posterior surface of ulna.

Nerve Supply: Radial nerve (C7, C8, T1). The nerve travels through the substance of the medial head of the triceps.

Action: Weak extensor of the elbow.

Brachioradialis

Origin

1. Upper two-thirds of lateral supracondylar ridge of humerus (Fig. 9.44).
2. Lateral intermuscular septum.

Insertion: Lateral side of radius just above the styloid process.

Nerve Supply: Radial nerve (C5, C6, C7).

Actions: Flexor of forearm, especially in the mid-prone position. It supinates the fully pronated forearm; and pronates the fully supinated forearm to bring it to the midprone position.)

Some Important Relations

1. The upper fleshy part of the muscle forms the lateral boundary of the cubital fossa. Here the radial nerve is deep to the muscle (between it and the brachialis).
2. Near its insertion its tendon is crossed by the tendons of the abductor pollicis longus and the extensor pollicis brevis.
3. At the wrist the radial artery is medial to the tendon (between it and the tendon of the flexor carpi radialis).
**Extensor Carpi Radialis Longus**

*Origin*
1. Lower one-third of the lateral supracondylar ridge of the humerus (Fig. 9.44).
2. Some fibres arises from the common extensor origin.
3. Some fibres from the lateral intermuscular septum.

*Insertion*: Dorsum of base of the second metacarpal bone.

*Nerve Supply*: Radial nerve (C6, C7).

*Actions*
1. Extension of wrist (along with the extensor carpi ulnaris).
2. Abduction of the wrist (along with the flexor carpi radialis).
3. Assists movements of the digits by fixing the wrist.

Also see extensor carpi radialis brevis, below.

**Extensor Carpi Radialis Brevis**

*Origin*
1. Common extensor origin (Fig. 9.44).
2. Radial collateral ligament of elbow. *Insertion:*
   Dorsal aspect of bases of second and third metacarpal bones.

*Nerve Supply*: Posterior interosseous nerve (C7, C8).

*Actions*: Same as those of extensor carpi radialis longus described above.

The extensor carpi radialis longus and brevis act as synergists with the flexors of the fingers when the fist is clenched, and stabilize the wrist. They act more often as synergists than as prime movers. The brevis is a better prime mover in pure wrist extension, and the longus is a better synergist in grasping or clenching.

The tendons of these two muscles pass through the same compartment of the extensor retinaculum, and have a common synovial sheath.

**Extensor Digitorum**

*Origin*: Common extensor origin (Fig. 9.44).

*Insertion*: The muscle ends in a tendon which splits into four parts, one for each digit other than the thumb. Over the proximal phalanx the tendon for each digit divides into three slips—one intermediate and two collateral. The intermediate slip is inserted into the dorsal aspect of the base of the middle phalanx. The collateral slips reunitie to be inserted into the dorsal aspect of the base of the distal phalanx. Also see dorsal digital expansion.

*Nerve Supply*: Posterior interosseous nerve (C7, C8).

*Actions*: Extension of interphalangeal, metacarpophalangeal and wrist joints.

**Additional Points**

1. The extensor digitorum and extensor indicis I pass through the same compartment of the extensor I retinaculum, and have a common synovial sheath.
2. The four tendons of the extensor digitorum I emerge from under cover of the extensor retinaculum and fan out over the dorsum of the hand. The tendon to the index finger is joined on its medial side by the tendon of the extensor indicis, and the tendon to the little finger is joined on its medial side by the I two tendons of the extensor digitii minimi.
3. On the dorsum of the hand adjacent tendons are variably connected together by three inter- I tendinous connections directed obliquely downwards and laterally. The medial connection is strong; the | lateral connection is weakest and may be absent.

The four tendons and three intertendinous con- | nections are embedded in deep fascia, and together form | the roof of the subtendinous (subaponeurotic) space on | the dorsum of the hand.

**Dorsal Digital Expansion**

The dorsal digital expansion (or extensor expansion) is a small triangular aponeurosis (related to each tendon of the extensor digitorum) covering the dorsum of the proximal phalanx. Its base, which is proximal, covers the metacarpophalangeal joint. The main tendon of the extensor digitorum occupies the central part of the extension, and is separated from the MP joint by a bursa.

The posterolateral corners of the extensor expansion are joined by tendons of the interosseus and of lumbrical muscles. The corners are attached to the deep transverse metacarpal ligament. The points of attachment of the interossei (proximal) and lumbrical (distal) are often called 'wing tendons'.

Near the proximal interphalangeal joint the extensor tendon divides into a central slip and two collateral slips. The central slip is joined by some fibres from the margins of the expansion, crosses the proximal interphalangeal joint, and is inserted on the dorsum of the base of the middle phalanx. The two collateral slips are joined by the remaining thick margin of the extensor expansion. They then join each other and are inserted on the dorsum of the base of the distal phalanx.

At the metacarpophalangeal and interphalangeal joints the extensor expansion forms the dorsal part of the fibrous capsule of the joints.
The retinacular ligaments (link ligaments) extend from the side of the proximal phalanx, and from its fibrous flexor sheath, to the margins of the extensor I expansion to reach the base of the distal phalanx.

**Wtetsor Digit! Minimi**

**Origin:** Common extensor origin (Fig. 9.44).

**Insertion:** The tendon joins the tendon of the extensor digitorum for the fifth digit. It is inserted through the dorsal digital expansion, into the dorsal aspect of the base of the middle phalanx, and the base of the distal phalanx.

**Nerve Supply:** Posterior interosseous nerve (C7, C8).

**Action:** Extension of the little finger at the interphalangeal and metacarpophalangeal joints. It can help in extending the wrist joint.

**Additional Points**

1. Extensor digiti minimi is usually fused with the extensor digitorum.
2. The tendon passes through a separate compartment of the extensor retinaculum, behind the radioulnar joint. On the dorsum of the hand the tendon divides into two parts which (with the tendon of the extensor digitorum) join the extensor expansion of the little finger.

**Extensor Carpi Ulnaris**

1. Common extensor origin (Fig. 9.44).
2. Posterior border of the ulna (by an aponeurosis common to it and to the flexor carpi ulnaris and the I flexor digitorum profundus).

**Insertion:** Medial side of the base of the fifth I metacarpal bone.

**Nerve supply:** Posterior interosseous nerve (C7, C8).

**Actions**

1. Extension of wrist along with the extensor I carpi radialis longus and brevis.
2. Adduction of the hand along with the flexor I carpi ulnaris.
3. Fixes the wrist during forceful movements of I the hand.

The tendon passes through a separate compartment of the extensor retinaculum, in the groove between the head and styloid process of the ulna.

**Muscles Inserted into Dorsal Digital Expansions of**

**Index Finger:** First dorsal interosseous, second palmar interosseous, first lumbrical, extensor I digitorum slip, and extensor indicis.

**Middle Finger:** Second and third dorsal interossei, second lumbrical, extensor digitorum slip.

**Ring Finger:** Fourth dorsal interosseous, third palmar interosseous, third lumbrical and extensor digitorum slip.

**Little Finger:** Fourth palmar interosseous, fourth lumbrical, extensor digitorum slip and extensor digit minimi.

**DEEP MUSCLES OF THE BACK OF THE FOREARM**

These are as follows (Fig. 9.45).

1. Supinator.
2. Abductor pollicis longus.
3. Extensor pollicis brevis.
4. Extensor pollicis longus.
5. Extensor indicis.

In contrast to the superficial muscles, none of the deep muscles cross the elbow joint. They arise from the radius, the ulna and the interosseous membrane.

Separate extensor carpi radials brevis from extensor digitorum and identify deeply placed supinator muscle.

Just distal to supinator is abductor pollicis longus. Other three muscles extensor pollicis longus, extensor pollicis brevis and extensor indicis are present distal to abductor pollicis longus. Identify them all.

**Supinator**

**Origin**

1. Lateral epicondyle of humerus.
2. Radial collateral ligament of the elbow joint.
3. Annular ligament.
4. Supinator crest of the ulna, and the posterior part of the triangular area in front of it (Fig. 9.45).

**Insertion:** Upper one-third of the lateral surface of the radius.

**Nerve Supply:** Posterior interosseous nerve (C6, C7).

**Action:** Supination of the forearm.

**Note:** The muscles have two layers, superficial and deep. The posterior interosseous nerve runs downwards between these layers.

**Abductor Pollicis Longus**

**Origin:** Upper parts of the posterior surfaces of the ulna and the radius, and from the interosseous membrane (Figs 9.45, 9.46).
The tendon usually splits into two parts: one part is attached to the lateral side of the base of the first metacarpal, and the other part is attached to the trapezium. Further fasciculi may become continuous with the opponens pollicis, or with the abductor pollicis brevis.

**Nerve Supply:** Posterior interosseous nerve (C7, C8).

**Action:** Abduction and extension of the thumb at the carpometacarpal joint.

See note under extensor pollicis brevis.

---

**Extensor Pollicis Longus**

*Origin:* Posterior surface of the ulna (below the origin of the abductor pollicis longus); and from the I interosseous membrane (Figs 9.45, 9.46).

*Insertion:* Base of distal phalanx of the thumb (dorsal aspect).

*Nerve Supply:* Posterior interosseous nerve (C7, C8).

*Action:* Extension at all joints of the thumb.

*Note:* The tendon of the extensor pollicis longus crosses the tendons of the extensor carpi radialis longus and brevis to reach the thumb.

The muscle may be absent, or completely fused with the abductor pollicis longus.

**Extensor Pollicis Brevis**

*Origin:* Posterior surface of the radius below the origin of the abductor pollicis longus; and from the interosseous membrane (Fig. 9.46).

*Insertion:* Dorsal surface of the base of the proximal phalanx of the thumb.

*Nerve Supply:* Posterior interosseous nerve (C7, C8).

*Action:* Extends the proximal phalanx and metacarpal of the thumb.

*Note:* The abductor pollicis longus and the extensor pollicis brevis are deep to the superficial extensors in
The tendons of the extensor carpi radialis longus and brevis emerge between the extensor carpi radialis longus and brevis and the extensor digitorum. They then cross the tendons of the extensor carpi radialis longus and brevis to reach their insertion.

**Extensor Indicis**

**Origin:** Posterior surface of the ulna below the origin of the extensor pollicis longus, and from the interosseous membrane.

**Insertion:** The tendon joins the ulnar side of the tendon of the extensor digitorum for the index finger.

**Nerve Supply:** Posterior interosseous nerve (C7 C8).

**Action:** Extension of the index finger. It helps to extend the wrist.

**Variations**

The muscle may send slips to the extensor tendons of other digits. Rarely its tendon may be interrupted, on the dorsum of the hand by an additional muscle belly called the extensor indicis brevis manus.

**Clinical Anatomy**

Paralysis of the extensor muscles of the forearm produces wrist drop. This is usually due to injury to the radial nerve above the level of the origin of the posterior interosseous nerve, for example in the axilla and arm.

Wrist drop is quite disabling because the patient cannot grip any object firmly in the hand without the synergistic action of the extensors (Fig. 9.47).

It is the chief nerve of the back of the forearm. It is a branch of the radial nerve given off in the cubital fossa, at the level of the lateral epicondyle of the humerus.

**Surface Marking**

Posterior interosseous nerve is marked by joining the following three points (Fig. 9.48).

(a) A point 1 cm lateral to the biceps tendon at the level of the lateral epicondyle.

(b) The second point; at the junction of the upper one-third and lower two-thirds of a line joining the middle of the posterior aspect of the head of the radius to the dorsal tubercle at the lower end of the radius (Lister's tubercle).

(c) The third point on the back of the wrist 1 cm medial to the dorsal tubercle.

Deep terminal branches of radial nerve and posterior interosseous artery:

Identify the posterior interosseous nerve at the distal border of exposed supinator muscle. Trace its branches to the various muscles. Look for the radial nerve in the lower lateral part of front of arm between the brachioradialis, extensor carpi radialis longus laterally and brachialis muscle medially. Trace the two divisions of this nerve in the lateral part of the cubital fossa. The deep branch (posterior interosseous nerve) traverses between the two planes of supinator muscle and reaches the back of the forearm where it is already identified.

The nerve runs amongst the muscles of the back of the forearm, and ends at the level of the wrist in a pseudoganglion.

This nerve is accompanied by posterior interosseous artery distal to the supinator muscle. This artery is supplemented by anterior interosseous artery in lower one-fourth of the forearm.

**Course and Relations**

1. Posterior interosseous nerve leaves the cubital fossa and enters the back of the forearm by passing between the two planes of fibres of the supinator. Within the muscle it winds backwards round the lateral side of the radius (Fig. 9.48, 9.49).
brevis, it passes deep to the extensor pollicis longus. It then runs on the posterior surface of the interosseous membrane up to the wrist where it enlarges into a pseudoganglion and ends by supplying the wrist and intercarpal joints.

**Branches and Distribution**

Posterior interosseous nerve gives muscular and articular branches (Fig. 9.50).

**(A) Muscular Branches**

(a) Before piercing the supinator, branches are given to the extensor carpi radialis brevis and to the supinator.
(b) While passing through the supinator another branch is given to the supinator.
(c) After emerging from the supinator, the nerve gives three short branches to: (i) the extensor digitorum, (ii) the extensor digiti minimi, and (iii) the extensor carpi ulnaris.

It also gives two long branches, (i) a lateral branch supplies the abductor pollicis longus and the extensor pollicis brevis, (ii) a medial branch supplies the extensor pollicis longus and the extensor indicis.
B Articular Branches
Articular branches are given to: (i) the wrist joint, (ii) [the distal radioulnar joint, and (iii) some intercarpal I and intermetacarpal joints.

I Sensory Branches
Sensory branches are given to the interosseous membrane, the radius and the ulna.

CLINICAL ANATOMY
The deep branch of the radial nerve may be damaged during an operation for exposure of the head of the radius. Since the extensor carpi radialis longus and brevis are spared wrist drop does not

THE POSTERIOR INTEROSSEOUS ARTERY
1. It is the smaller terminal branch of the common interosseous artery in the cubital fossa.
2. It enters the back of the forearm by passing between the oblique cord and the upper margin of the interosseous membrane (Fig. 9.49).
3. It appears on the back of the forearm in the interval between the supinator and the abductor pollicis longus and thereafter accompanies the posterior interosseous nerve. At the lower border of the extensor indicis, the artery becomes markedly reduced and ends by anastomosing with the anterior interosseous artery which reaches the posterior compartment by piercing the interosseous membrane at the upper border of the pronator quadratus. Thus in its lower one-fourth the back of the forearm is supplied by the anterior interosseous artery.
4. The posterior interosseous artery gives off an interosseous recurrent branch which runs upwards and takes part in the anastomosis on the back of the lateral epicondyle of the humerus.
Joints are sites where two or more bones or cartilages articulate. Free movements occur at the synovial joints. Shoulder joint is the most freely mobile joint. Shoulder joints get excessive mobility at the cost of its own stability, since both are not feasible to the same degree. The carrying angle in relation to elbow joint is to facilitate carrying objects like buckets without hitting the pelvis.

Supination and pronation are basic movements for the survival of human being. During pronation the food is picked and by supination it is put at the right place-the mouth. While 'giving', one pronates, while 'getting' one supinates.

The first carpometacarpal joint allows movements of opposition of thumb with the fingers for picking up or holding things. Thumb is the most important digit. Remember Muni Dronacharya asked Eklavya to give his right thumb as Guru-Dakshina, so that he [is not able to outsmart Arjuna in archery.

THE SHOULDER GIRDLE

The shoulder girdle connects the upper limb to the axial skeleton. It consists of the clavicle and the scapula. Anteriorly, the clavicle reaches the sternum and articulates with it at the sternoclavicular joint. The clavicle and the scapula are united to each other at the acromioclavicular joint. The scapula is not connected to the axial skeleton directly, but is attached to it through muscles. The clavicle and the scapula have been studied. The joints of the shoulder girdle are described below.

Sternoclavicular Joint

The sternoclavicular joint is a synovial joint. It is a compound joint as there are three elements taking part in it; namely the medial end of the clavicle, the
Remove the subclavius muscle from first rib at its attachment with its costal cartilage. Identify the costoclavicular ligament.

Define the sternoclavicular joint and clean the anterior and superior surfaces of the capsule of this joint. Cut carefully through the joint to expose the intra-articular disc positioned between the clavicle and the sternum. The fibrocartilaginous disc divides the joint cavity into a superomedial and an inferolateral compartments.

clavicular notch of the manubrium sterni, and the upper surface of the first costal cartilage. It is a complex joint as its cavity is subdivided into two parts by an intra-articular disc (Fig. 10.1).

The articular surface of the clavicle is covered with fibrocartilage (as the clavicle is a membrane bone). The surface is convex from above downwards and slightly concave from front to back. The sternal surface is smaller than the clavicular surface. It has a reciprocal convexity and concavity. Because of the concavo-convex shape of the articular surfaces, the joint can be classified as a saddle joint.

The capsular ligament is attached laterally to the margins of the clavicular articular surface; and medially to the margins of the articular areas on the sternum and on the first costal cartilage. It is strong anteriorly and posteriorly where it constitutes the anterior and posterior sternoclavicular ligaments.

However, the main bond of union at this joint is the articular disc. The disc is attached laterally to the clavicle on a rough area above and posterior to the articular area for the sternum. Interiorly, the disc is attached to the sternum and to the first costal cartilage at their junction. Anteriorly and posteriorly the disc fuses with the capsule.
There are two other ligaments associated with this joint. The interclavicular ligament passes between the sternal ends of the right and left clavicles, some of its fibres being attached to the upper border of the manubrium sterni. The costoclavicular ligament is attached above to the rough area on the inferior aspect of the medial end of the clavicle.

Interiorly, it is attached to the first costal cartilage and to the first rib. It consists of anterior and posterior laminae.

Blood Supply: Internal thoracic and suprascapular arteries

Nerve Supply: Medial supraclavicular nerve.

Movements: See movements of shoulder girdle, below.

**Acromioclavicular Joint**

The acromioclavicular joint is a plane synovial joint. It is formed by articulation of small facets present: (i) at the lateral end of the clavicle, and (ii) on the medial end of the acromion process of the scapula. The facets are covered with fibrocartilage. The cavity of the joint is occasionally subdivided by an articular disc which may have perforation in it.

---

**DISSECTION**

Remove the muscles attached to the lateral end of the clavicle and acromial process of the scapula. Define the articular capsule surrounding the joint. Cut through the capsule to identify the intra-articular disc. Look for the strong coracoclavicular ligament.

The bones are held together by a fibrous capsule and by the articular disc. However, the main bond of union between the scapula and the clavicle is the coracoclavicular ligament described below (Fig. 10.1). (a) Articular disc is complete. (b) Articular disc may be perforated.

**Blood Supply:** Suprascapular and acromial arteries.

**Nerve Supply:** Lateral supraclavicular nerve.

**Movements:** See movements of shoulder girdle.

---

**Coracoclavicular Ligament**

The ligament consists of two parts: conoid and trapezoid. The conoid part is attached, below to the upper surface of the scapula; and above to the costal end of the lateral part of the clavicle. The trapezoid part is attached, below, to the root of the coracoid process just lateral to the scapular notch. It is attached above to the articular surface of the clavicle on the conoid tubercle.

**Movements of the Shoulder Girdle**

Movements at the two joints of the girdle are always associated with the movements of the scapula (Fig. 10.2a). The movements of the scapula may or may not be associated with the movements of the shoulder joint. The various movements are described below.

1. **Elevation** of the scapula (as in shrugging the shoulders). It is brought about by the pectoralis major. It is associated with the elevation of the upper fibres of the serratus anterior and by the pectoralis minor. It is associated with the elevation of the scapula (Fig. 10.2a).

2. **Depression** of the scapula (drooping of the shoulder). It is brought about by gravity, and actively by the lower fibres of the serratus anterior and by the pectoralis minor. It is associated with the depression of the lateral end and elevation of the medial end of the clavicle (Fig. 10.2c).

3. **Protraction** of the scapula (as in pushing an object away). It is brought about by the serratus anterior and by the pectoralis minor. It is associated with forward movements of the lateral end and backward movement of the medial end.

4. **Retraction** of the scapula (squaring the shoulders). It is brought about by the rhomboideus and biceps, the middle fibres of the trapezius. It is associated with backward movement of the medial end and forward movement of the medial end of the clavicle.

---
5. Forward rotation of the scapula round the chest wall takes place during overhead abduction of the arm. The scapula rotates round the coracoclavicular ligaments. The movement is brought about by the upper fibres of the trapezius and the lower fibres of the serratus anterior. This movement is associated with rotation of the clavicle around its long axis (Fig. 10.2f).

Fig. 10.2: Movements of the right shoulder girdle. Figure (a) shows the anatomical position. The dotted scapulae in figures (b–f) are also in anatomical position. The overlying scapulae show their respective movement.
6. **Backward rotation** of the scapula occurs under the influence of gravity, although it can be brought about actively by the levator scapulae and the rhomboideus. This is associated with rotation of the clavicle in a direction opposite to that during forward rotation.

**CLINICAL ANATOMY**

1. The clavicle may be dislocated at either of its ends. At the medial end, it is usually dislocated forwards. Backward dislocation is rare as it is prevented by the costoclavicular ligament.

2. The main bond of union between the clavicle and the manubrium is the articular disc. Apart from its attachment to the joint capsule, the disc is also attached above to the medial end of the clavicle and below to the manubrium. This prevents the sternal end of the clavicle from tilting upwards when the weight of the arm depresses the acromial end.

3. The clavicle dislocates upwards at the acromioclavicular joint, because the clavicle overrides the acromion.

4. The weight of the limb is transmitted from the scapula to the clavicle through the coraco-clavicular ligament, and from the clavicle to the sternum through the sternoclavicular joint. Some of the weight also passes to the first rib by the costoclavicular ligament. The clavicle usually fractures between these two ligaments.

**Ligaments of the Scapula**

Figure 10.3 shows details of the ligaments of scapula. The *coracoacromial ligament* (see Fig. 7.8). It is a triangular ligament, the apex of which is attached to the tip of the acromion, and the base to the lateral border of the coracoid process.

The acromion, the coracoacromial ligament and the coracoid process, together form the *coracoacromial arch*, which is known as the secondary socket for the head of the humerus. It adds to the stability of the joint and protects the head of the humerus.

The *superior transverse scapular or suprascapular ligament*. It converts the scapular notch into a foramen. The suprascapular nerve passes below the ligament, and the suprascapular artery above the ligament (Fig. 10.3).

The *inferior transverse scapular (spinoglenoid) ligament*. It is a weak band which bridges the spinoglenoid notch. The suprascapular nerve and vessels pass beneath the arch to enter the infraspinous fossa.

**Surface Marking**

The anterior margin of the glenoid cavity corresponds to the lower half of the shoulder joint. It is marked by a line 3 cm long drawn downwards from a point just lateral to the tip of the coracoid process. The line is slightly concave laterally.

Having studied all the muscles at the upper end of the scapula it is wise to open and peep into the most mobile shoulder joint.

Identify the muscles attached to the greater and lesser tubercles of humerus. Deep to the acromion look for the subacromial bursa.

Identify coracoid process, acromion process and triangular coracoacromial arch binding these two bones together. Trace the supraspinatus muscle from supraspinous fossa of scapula to the greater tubercle of humerus. On its way it is intimately fused to the capsule of the shoulder joint. In the same way, tendons of infraspinatus and teres minor also fuse with the posterior part of the capsule. Inferiorly trace the tendon of long head of triceps brachii from the infraglenoid tubercle of scapula.

Cut through the subscapularis muscle at the neck of scapula. It also gets fused with the anterior part of capsule of the shoulder joint as it passes to the lesser tubercle of humerus.

**Type**

The shoulder joint is a synovial joint of the ball and socket variety.
I Articular Surface

The joint is formed by articulation of the scapula and head of the humerus. Therefore, it is also known as the glenohumeral articulation. Structurally, it is a weak joint because the glenoid cavity is too small and shallow to hold the head of the humerus in place. (The head is four times the size of the glenoid cavity.) However, this arrangement permits great mobility. Stability of the joint is maintained by the following factors.

1. The coracoacromial arch or secondary socket for the head of the humerus (Fig. 7.8).
2. The musculotendinous cuff of the shoulder (Fig. 7.7).
3. The glenoidal labrum helps in deepening the glenoid fossa. Stability is also provided by the muscles attaching the humerus to the pectoral girdle, the long head of the biceps, the long head of the triceps, and atmospheric pressure.

I Ligaments of the Joint

As the articular capsule is opened, the three gleno-humeral ligaments are noticeable on the anterior part of the capsule. Define the articular surfaces, ligaments, bursae related to this important joint.

1. The capsular ligament: It is very loose and permits free movements. It is least supported inferiorly where dislocations are common. Such a dislocation may damage the closely related axillary nerve (Fig. 7.10).

Medially, the capsule is attached to the scapula beyond the supraglenoid tubercle and the margins of the labrum. Laterally, it is attached to the anatomical neck of the humerus with the following exceptions. Interiorly, the attachment extends down to the surgical neck. Superiorly, it is deficient for passage of the tendon of the long head of the biceps brachii. The joint cavity communicates with the subscapular bursa, with the synovial sheath for the tendon of the long head of the biceps brachii, and often with the infraspinatus bursa. Anteriorly, the capsule is reinforced by supplemental bands called the superior, middle, and inferior glenohumeral ligaments. The capsule is lined with synovial membrane. An extension of this membrane forms a tubular sheath for the tendon of the long head of the biceps brachii.

1. The coracohumeral ligament: It extends from the root of the coracoid process to the neck of the humerus opposite the greater tubercle. It gives strength to the capsule.
2. The transverse humeral ligament: It bridges the upper part of the bicipital groove of the humerus (between the greater and lesser tubercles). The tendon of the long head of the biceps brachii passes deep to the ligament.
3. The glenoidal labrum: It is a fibrocartilaginous rim which covers the margins of the glenoid cavity, thus increasing the depth of the cavity.

Bursae Related to the Shoulder Joint

1. The subacromial (subdeltoid) bursa (Figs 7.8, 7.9).
2. The subscapularis bursa, communicates with the joint cavity.

1. The infraspinatus bursa, may communicate with the joint cavity.
2. Several other bursae related to the coracobrachialis, teres major, long head of the triceps, latissimus dorsi, and the coracoid process are present.

Relations

Superiorly. Coracoacromial arch, subacromial bursa, supraspinatus and deltoid (Fig. 10.4).
Posteriorly. Infraspinatus, teres minor and deltoid. Within the joint: Tendon of the long head of the biceps brachii.

Blood Supply

1. Anterior circumflex humeral vessels,
2. Posterior circumflex humeral vessels,
3. Suprascapular vessels, and
4. Subscapular vessels.

Nerve Supply

1. Axillary nerve,
2. Musculocutaneous nerve, and
3. Suprascapular nerve.
MOVEMENTS AT THE SHOULDER JOINT

**Fig. 10.4:** Schematic sagittal section showing relations of the shoulder joint.

**Fig. 10.5:** Planes of movements of the shoulder joint.
The shoulder joint enjoys great freedom of mobility at the cost of stability. There is no other joint in the body which is more mobile than the shoulder. This wide range of mobility is due to laxity of its fibrous capsule, and the large size of the head of the humerus as compared with the shallow glenoid cavity. The range of movements is further increased by concurrent movements of the shoulder girdle (Figs 10.5, 10.6).
Movements of the shoulder joint are considered in relation to the scapula rather than in relation to the sagittal and coronal planes. When the arm is by the side (in the resting position) the glenoid cavity faces almost equally forwards and laterally; and the head of the humerus faces medially and backwards. Keeping these directions in mind, the movements are analyzed as follows.

1. **Flexion and extension.** During flexion the arm moves forwards and medially, and during extension it the arm moves backwards and laterally. Thus flexion and extension take place in a plane parallel to the surface of the glenoid cavity (Figs 10.6.1, 10.6.2).

2. **Abduction and adduction** take place at right angles to the plane of flexion and extension, i.e. approximately midway between the sagittal and coronal planes. In abduction, the arm moves anterolateral away from the trunk. This movement is in the same plane as that of the body of the scapula (Figs 10.6.3, 10.6.4).

3. **Medial and lateral rotation** are best demonstrated with a midflexed elbow. In this position, the hand is moved medially in medial rotation, and laterally in lateral rotation of the shoulder joint (Figs 10.6.5, 10.6.6).

4. **Circumduction** is a combination of different movements as a result of which the hand moves along a circle.

The range of any movement depends on the availability of an area of free articular surface on the head of the humerus. It may be noted that the articular area on the head of the humerus is four times larger than that on the glenoid cavity.
Muscles Producing Movements

1. **Flexion** is brought about:
   (a) Mainly by the clavicular part of the pectoralis major, the anterior fibres of the deltoid, and the coracobrachialis (Table 10.1).
   (b) Is assisted by the coracobrachialis and short head of the biceps.

2. **Extension**
   (a) In the resting position, extension is brought about by the posterior fibres of the deltoid, the teres major, and latissimus dorsi.
   (b) A fully flexed arm is brought back to the plane of the body by the sternocostal part of the pectoralis major (against resistance).

3. **Abduction** of the arm is brought about by the supraspinatus, the deltoid, the serratus anterior, and the upper and lower fibres of the trapezius. The abduction is initiated by supraspinatus and is taken over by the deltoid which exerts an upward pull on the head of the humerus. This is counteracted by a downward pull produced by the subscapularis, the infraspinatus and the teres minor (thus avoiding upward displacement of the head of the humerus). Thus the deltoid and these three muscles constitute a 'couple' which permits true abduction in the plane of the body of the scapula. The serratus anterior and the trapezius increase the range of the abduction considerably up to 180 degrees by rotating the! scapula so that the glenoid cavity faces upwards!)

1. **Adduction** is brought about: (a) mainly by the pectoralis major and the latissimus dorsi; and (b) is assisted by the teres major, the coracobrachialis, the short head of the biceps brachii, and the long head of the triceps brachii.

2. **Medial rotation** is produced by the pectoralis major, the anterior fibres of the deltoid, the latissimus dorsi, and the teres major. When the arm is by the side the movement is also assisted by the sub- scapularis.

3. **Lateral rotation** is produced by the posterior fibres of the deltoid, the infraspinatus, and the teres minor.

**Analysis of Abduction at the Shoulder**

Abduction at the shoulder occurs through 180 degrees. The movement takes place partly at the shoulder joint and partly at the shoulder girdle (forward rotation of scapula round the chest wall). The humerus and scapula move in the ratio of 2: 1 throughout abduction. For every 15 degrees of elevation, 10 degrees occur at the shoulder joint and

</table>
5 degrees are due to movement of the scapula. Rotation of the scapula is facilitated by movements at the sternoclavicular and acromioclavicular joints.

The articular surface of the head of the humerus permits abduction of the arm only up to 90 degrees. At the limit of this movement there is lateral rotation of the humerus and the head of the bone comes to lie deep to the coracoacromial arch.

Abduction is initiated by the supraspinatus, but the deltoid is the main abductor. The scapula is rotated by combined action of the trapezius and serratus anterior.

**CLINICAL ANATOMY**

1. **Dislocation.** The shoulder joint is more prone to dislocation than any other joint. This is due to laxity of the capsule and the disproportionate area of the articular surfaces. Dislocation usually occurs when the arm is abducted. In this position, the head of the humerus presses against the lower unsupported part of the capsular ligament. Thus almost always the dislocation is primarily subglenoid, but later it may become subcoracoid, subclavicular, or subspinous. Dislocation endangers the axillary nerve which is closely related to the lower part of the joint capsule.

2. **Optimum attitude.** In order to avoid ankylosis, many diseases of the shoulder joint are treated in an optimum position of the joint. In this position, the arm is abducted by 45-90 degrees.

3. **Shoulder tip pain.** Irritation of the diaphragm from any surrounding pathology causes referred pain in the shoulder. This is so because the phrenic nerve (supplying the diaphragm) and the supraclavicular nerves (supplying the skin over the shoulder) both arise from spinal segments C3, C4.

4. The shoulder joint is most commonly approached (surgically) from the front. However, for aspiration the needle may be introduced either anteriorly through the deltopectoral triangle (closer to the deltoid), or laterally just below the acromion.

5. **Frozen shoulder.** This is a common occurrence. Pathologically, the two layers of the synovial membrane become adherent to each other. Clinically, the patient (usually 40-60 years of age) complains of progressively increasing pain in the shoulder, stiffness in the joint and restriction of all movements. The surrounding muscles show disuse atrophy. The disease is self-limiting and the patient may recover spontaneously in about two years.

6. Shoulder joint disease can be excluded if the patient can raise both his arms above the head and bring the two palms together.

Continuous pain throughout abduction indicates some kind of arthritis: pain between 60-120 degrees of abduction suggests supraspinatus tendinitis, or subacromial bursitis; and abduction limited to 40-50 degree suggests tear of the supraspinatus tendon.

**THE ELBOW JOINT**

The elbow joint is a synovial joint between the lower end of humerus and the upper ends of radius and ulna bones.

**DISSECTION**

Cut through the muscles arising from the lateral and medial epicondyles of humerus and reflect them distally if not already done. Also cut through biceps brachii, brachialis and triceps brachii 3 cm proximal to the elbow joint and reflect them distally. Remove all the muscles fused with the fibrous capsule of the elbow joint and define its attachments.

Define the articular surfaces, ligaments and relations of the joint.

**Surface Marking**

The joint line is situated 2 cm below the line joining the two epicondyles, and slopes downwards and medially. This slope is responsible for the carrying angle.

**Type:** This is a synovial joint of the hinge variety.

**Articular Surfaces**

**Upper:** The capitulum and trochlea of the humerus.

**Lower:** (i) Upper surface of the head of the radius articulates with the capitulum, (ii) trochlear notch of the ulna articulates with the trochlea of the humerus (Fig. 10.7).

The elbow joint is continuous with the superior radioulnar joint. The humeroradial, the humeroulnar and the superior radioulnar joints are together known as cubital articulations.

**Ligaments**

1. Capsular ligament. **Superiorly,** it is attached to the lower end of the humerus in such a way that the
capitulum, the trochlea, the radial fossa, the coronoid fossa and the olecranon fossa are intracapsular. Inferomedially, it is attached to the margin of the trochlear notch of the ulna except laterally; inferolaterally, it is attached to the annular ligament of the superior radioulnar joint. The synovial membrane lines the capsule and the fossae, named above.

1. The anterior ligament and
2. The posterior ligament are thickening of the capsule.
3. The ulnar collateral ligament is triangular in shape (Fig. 10.8). Its apex is attached to the medial epicondyle of the humerus, and its base to the ulna. The ligament has thick anterior and posterior bands: these are attached below to the coronoid process and the olecranon respectively. Their lower ends are joined to each other by an oblique band which gives attachment to the thinner intermediate fibres of the ligament. The ligament is crossed by the ulnar nerve and gives origin to the flexor digitorum superficialis. It is closely related to the flexor carpi ulnaris and the triceps brachii.

5. The radial collateral or lateral ligament. It is a fan-shaped band extending from the lateral epicondyle to the annular ligament. It gives origin to the supinator and to the extensor carpi radialis brevis (Fig. 10.9).

Relations of Elbow Joint

Anteriorly: Brachialis, median nerve, brachial artery and tendon of biceps (Fig. 9.15).
Posteriorly: Triceps and anconeus.
Medially: Ulnar nerve, flexor carpi ulnaris and common flexors.
Laterally: Supinator, extensor carpi radialis brevis and other common extensors.

Blood Supply

From anastomosis around the elbow joint.

Nerve Supply

The joint receives branches from the following nerves: (i) ulnar nerve, (ii) median nerve, (iii) radial nerve, and (iv) musculocutaneous nerve through its branch to the brachialis.

Movements

1. Flexion is brought about by: (i) the brachialis, (ii) the biceps, and (iii) the brachioradialis.
2. Extension is produced by: (i) the triceps, and (ii) the anconeus.
The transverse axis of the elbow joint is directed medially and downwards. Because of this the extended forearm is not in straight line with the arm, but makes an angle of about 163 degrees with it. This is known as the carrying angle. The factors responsible for production of the carrying angle are as follows.

(a) The medial flange of the trochlea is 6 mm deeper than the lateral flange.

(b) The superior articular surface of the coronoid process of the ulna is placed oblique to the long axis of the bone.

The carrying angle disappears in full flexion of the elbow, and also during pronation of the forearm. The forearm comes into line with the arm in the midprone position, and this is the position in which the hand is mostly used. This arrangement of gradually increasing carrying angle during extension of the elbow increases the precision with which the hand (and objects held in it) can be controlled.

**THE RADIOULNAR JOINTS**

Remove all the muscles covering the adjacent sides of radius, ulna and the intervening interosseous membrane. This will expose the superior and inferior radioulnar joints including the interosseous membrane.

Cut through the annular ligament to see the superior radioulnar joint. Clean and define the interosseous membrane. Lastly cut through the capsule of inferior radioulnar joint to locate the intraarticular fibrocartilaginous disc of the joint. Learn the movements of supination and pronation on dry bones and on yourself.

---

**CLINICAL ANATOMY**

1. **Distension** of the elbow joint by an effusion occurs posteriorly because here the capsule is weak and the covering deep fascia is thin. Aspiration is done posteriorly on any side of the olecranon.

2. **Dislocation** of the elbow is usually posterior, and is often associated with fracture of the coronoid process. The triangular relationship between the olecranon and the two humeral epicondyles is lost.

1. **Subluxation** of the head of the radius (pulled elbow) occurs in children when the forearm is suddenly pulled in pronation. The head of the radius slips out from the annular ligament.

2. **Tennis elbow.** Abrupt pronation may lead to pain and tenderness over the lateral epicondyle. This is possibly due to: (i) sprain of radial collateral ligament, and (ii) tearing of fibres of the extensor carpi radialis brevis.

3. **Miner’s (or student’s elbow)** is characterized by effusion into the bursa over the subcutaneous posterior surface of the olecranon process.

4. **Optimum position** of the elbow. If only elbow is to be fixed it is flexed at right angle. If both elbows need fixation the right elbow is fixed in a position of flexion at an angle slightly less than 90 degrees, and the left elbow at an angle slightly more than 90 degrees. In this position, the right hand can be brought to the mouth and the left hand can be used for cutting up food. It can also reach the trouser pocket.

anterior and posterior margins of the radial notch of the ulna. The upper border of the ligament is continuous with the fibrous capsule of the elbow joint (except posteriorly where the capsule passes deep to the annular ligament to be attached to the posterior and inferior margins of the radial notch). From the lower border of the annular ligament, some fibres pass over the synovial membrane to be loosely attached to the neck of the radius.

A thin fibrous layer, often termed the quadrate ligament, covers the synovial membrane and closes the joint cavity from below, between the radius and the ulna.

The superficial surface of the annular ligament blends with the radial collateral ligament of the elbow, gives origin to the supinator muscle, and is related to the anconeus and to the interosseous recurrent artery. The inner surface of the upper part of the ligament is covered with cartilage, and in its lower part it is lined with synovial membrane.

2. Articular Disc of Inferior Radioulnar Joint

The disc shows age changes. With advancing age the disc undergoes progressive degeneration characterized by reduced cellularity, loss of elastic fibres, mucoid degeneration of ground substance, exposure of collagen fibres, fibrillation, thinning, and ultimately perforation. Perforation occurs only after the second decade of life.

Interosseous Membrane

The interosseous membrane connects the shafts of I the radius and ulna. It is attached to the interosseous I borders of these bones. The fibres of the membrane I run downwards and medially from the radius to ulna I (Fig. 10.10). The two bones are also connected by the I oblique cord which extends from the tuberosity of I the radius to the tuberosity of the ulna. The direction of its fibres is opposite to that in the interosseous membrane.

(a)Superiorly, the interosseous membrane begins 2-3 cm below the radial tuberosity. Between the I oblique cord and the interosseous membrane there is a gap for passage of the posterior interosseous vessels to the back of the forearm.

(b)Interiorly, a little above its lower margin, there is an aperture for the passage of the anterior interosseous vessels to the back of the forearm.

(c)The anterior surface is related to the flexor pollicis longus, the flexor digitorum profundus, the pronator quadratus, and to the anterior interosseous vessels and nerve (Fig. 2.27).

(d)The posterior surface (Fig. 9.45) is related to the supinator, the abductor pollicis longus, the extensor pollicis brevis, the extensor pollicis longus, the extensor indicis, the anterior interosseous artery and the posterior interosseous nerve.
The interosseous membrane performs the following functions.
1. It binds the radius and ulna to each other.
2. It provides attachments to many muscles.
3. It transmits forces (including weight) applied to the radius (through the hand) to the ulna. This transmission is necessary as radius is the main bone taking part in the wrist joint, while the ulna is the main bone taking part in the elbow joint.

**Supination and Pronation**

Supination and pronation are rotatory movements of the forearm (and hand) around a vertical axis. In a semiflexed elbow, the palm is turned upwards in supination, and downwards in pronation (kings pronate, beggars supinate). The movements are permitted at the superior and inferior radioulnar joints.

The vertical axis of movement of the radius passes through the centre of the head of the radius above, and through the ulnar attachment of the articular disc below. However, this axis is not stationary because the lower end of the ulna is not fixed: it moves backwards and laterally during pronation, and forwards and medially during supination. As a result of this movement, the axis (defined above) is displaced laterally in pronation, and medially in supination. For the same reason, the axis of pronation and supination passes between the radius and ulna at both joints when there is marked ulnar movement; and through the centre of the head of the radius and the ulnar styloid process when ulnar movement is minimal. Inferiorly, the axis may pass through any digit depending on the degree of medial or lateral displacement of the lower end of the ulna.

Supination is more powerful than pronation because it is an antigravity movement. Supination movements are responsible for all screwing movements of the hand, e.g. as in tightening nuts and bolts. Morphologically, pronation and supination were evolved for picking up food and taking it to the mouth.

Pronation is brought about chiefly by the pronator quadratus. It is aided by the pronator teres when the movement is rapid and against resistance. Gravity also helps (Fig. 10.11).

Supination is brought about by the supinator muscle and the biceps brachii. Slow supination, with elbow extended, is done by the supinator. Rapid supination with the elbow flexed, and when performed against resistance, is done mainly by the biceps (Fig. 10.12).
Cut through the thenar and hypothenar muscles from their origins and reflect them distally. Separate the flexor and extensor retinacula of the wrist from the bones. Cut through flexor and extensor tendons (if not already done) and reflect them distally.

Define the capsular attachments and ligaments and relations of the wrist joint.

**Surface Marking**

The joint line is obtained by joining the styloid processes of the radius and ulna. It is convex upwards. The joint neither communicates with the inferior radio-ulnar joint nor with the intercarpal joints.

**Articular Surfaces**

**Upper**
1. Inferior surface of the lower end of the radius (Fig. 2.24)
2. Articular disc of the inferior radio-ulnar joint (Fig. 10.13).

**Lower**
1. Scaphoid
2. Lunate
3. Triquetral bones.

**Ligaments**
1. The *articular capsule* surrounds the joint. It is attached above to the lower ends of the radius and ulna, and below to the proximal row of carpal bones. A protrusion of synovial membrane, called the *prestyloid recess*, lies in front of the styloid process of the ulna and in front of the articular disc. It is bounded inferiorly by a small meniscus projecting inwards from the ulnar collateral ligament between the styloid process and the triquetral bone. The *ulnar collateral ligament* is strengthened by the following ligaments.

2. On the palmar aspect there are two palmar carpal ligaments.

   The *palmar radiocarpal ligament* is a broad band. It begins above from the anterior margin of the lower end of the radius and its styloid process, runs downwards and medially, and is attached below to the anterior surfaces of the scaphoid, lunate and triquetral bones.

   The *palmar ulnocarpal ligament* is a rounded fasciculus. It begins above from the base of the styloid process of the ulna and the anterior margin of the articular disc, runs downwards and laterally, and is attached to the lunate and triquetral bones.

   Both the palmar carpal ligaments are considered to be intracapsular.

3. On the dorsal aspect of the joint there is one *dorsal radiocarpal ligament*. It is weaker than the palmar ligaments. It begins above from the posterior margin of the lower end of the radius, runs downwards and medially, and is attached below to the dorsal surfaces of the scaphoid, lunate and triquetral bones.

   The *radial collateral ligament* extends from the tip of the styloid process of the radius to the lateral side of the scaphoid bone. It is related to the radial artery (Fig. 10.13).

   The *ulnar collateral ligament* extends from the tip of the styloid process of the ulna to the triquetral and pisiform bones.

   Both the collateral ligaments are poorly developed.

**Relations**

**Anterior.** Long flexor tendons with their synovial sheaths, and median nerve.

**Posterior.** Extensor tendons of the wrist and fingers with their synovial sheaths.

**Lateral.** Radial artery.

**Blood Supply**

Anterior and posterior carpal arches.

**Nerve Supply**

Anterior and posterior interosseous nerves.
Movements at the wrist are usually associated with the movements at the midcarpal joint. The active movements are described.

1. **Flexion**: It takes place more at the midcarpal than at the wrist joint. The main flexors are: (i) the flexor carpi radialis, (ii) the flexor carpi ulnaris, and (iii) the palmaris longus. The movement is assisted by the long flexors of the fingers and thumb (Fig. 10.14), and the abductor pollicis longus.

2. **Extension**: It takes place mainly at the wrist joint. The main extensors are: (i) the extensor carpi radialis longus, (ii) the extensor carpi radialis brevis, and (iii) the extensor carpi ulnaris. It is assisted by the extensors of the fingers and thumb (Fig. 10.15).

3. **Abduction**: It occurs mainly at the midcarpal joint. The main abductors are: (i) the flexor carpi radialis, (ii) the extensor carpi radialis longus and brevis, and (iii) the abductor pollicis longus and the extensor pollicis brevis.

4. **Adduction**: It occurs mainly at the wrist joint. The main adductors are: (i) the flexor carpi ulnaris, and (ii) the extensor carpi ulnaris.

5. **Circumduction**: The range of flexion is more than that of extension. Similarly, the range of adduction is greater than abduction (due to the longer styloid process of the radius).

**CLINICAL ANATOMY**

1. The wrist joint is commonly involved in rheumatoid arthritis, in which collagen tissue is mostly affected.

2. The back of the wrist is the common site for a ganglion. It is a cystic swelling resulting from mucoid degeneration of synovial sheaths around the tendons.

3. The wrist joint can be aspirated from the posterior surface between the tendons of the extensor pollicis longus and the extensor indicis.

4. The joint is immobilized in optimum position of 30 degree dorsiflexion (extension).

**JOINTS OF THE HAND**

**INTERCARPAL, CARPOMETACARPAL AND INTERMETACARPAL JOINTS**

There are three joint cavities among the intercarpal, carpometacarpal and intermetacarpal joints, which are: (1) pisotriquetral, (2) first carpometacarpal, and (3) a common cavity for the rest of the joints. The
common cavity may be described as the midcarpal (transverse intercarpal) joint between the proximal and distal rows of the carpus, which communicates with intercarpal joints superiorly, and with intercarpal, carpometacarpal and intermetacarpal joints inferiorly (Fig. 10.13).

The midcarpal joint permits movements between the two rows of the carpus as already described with the wrist joint.

### DISSECTION

Intercarpal, carpometacarpal and intermetacarpal joints:

Out of these the most important joint with a separate joint cavity is the first carpometacarpal joint. This is the joint of the thumb and a wide variety of functionally useful movements take place here. Identify the distal surface of trapezium and base of first metacarpal bone. Define the metacarpophalangeal and interphalangeal joints.

For their dissection remove all the muscles and tendons from the anterior and posterior aspects of any two metacarpophalangeal joint. Define the articular capsule and ligaments. Do the same for proximal and distal interphalangeal joints of one of the fingers and define the ligaments.

#### FIRST CARPOMETACARPAL JOINT

First carpometacarpal joint is only carpometacarpal joint which has a separate joint cavity. Movements at this joint are, therefore, much more free than at any other corresponding joint.

**Type**

Saddle variety of synovial joint (because the articular surfaces are concavo-convex).

**Articular Surfaces**

(i) The distal surface of the trapezium (ii) The proximal surface of the base of the first metacarpal bone. The concavo-convex nature of the articular surfaces permits a wide range of movements (Fig. 10.13).

**Ligaments**

1. Capsular ligament. Surrounds the joint. In general, it is thick but loose, and is thickest dorsally and laterally.
2. Lateral ligament. A broad band which strengthens flap pancnlp lat*vrnl1-\r

1. The anterior ligament
2. The posterior ligaments are oblique bands running downwards and medially.

**Relations**

Anteriorly, the joint is covered by the muscles of the thenar eminence. Posteriorly, there are long and short extensors of the thumb. Medially there is the first dorsal interosseous muscle, and the radial artery! (passing from the dorsal to the palmar aspect of the hand through the interosseous space). Laterally, there is the tendon of the abductor pollicis longus.

**Blood Supply**

Radial vessels supply blood to the synovial membrane and capsule of the joint.

**Nerve Supply**

First digital branch of median nerve supplies the capsule of the joint.

**Movements**

Flexion and extension of the thumb take place in the plane of the palm, and abduction and adduction at right angles to the plane of the palm. In apposition, the thumb crosses the palm and touches other fingers. Flexion is associated with medial rotation, and extension with lateral rotation at the joint.

Circumduction is a combination of different movements mentioned. The following muscles bring about the movements (Figs 10.16, 10.17).

1. Flexion. (i) Flexor pollicis brevis
   (ii) Opponens pollicis.
2. Extension. (i) Abductor pollicis longus
   (ii) Extensor pollicis brevis (iii) Extensor pollicis longus.
3. Abduction. (i) Abductor pollicis brevis
   (ii) Abductor pollicis longus.
4. Adduction. Adductor pollicis
5. Opposition. (i) Opponens pollicis
   (ii) Flexor pollicis brevis.

The adductor pollicis and the flexor pollicis longus exert pressure on the opposed fingers.

#### METACARPOPHALANGEAL JOINTS

**Type**

Metacarpophalangeal joints are synovial joints of the condylar variety.
Ligaments

Each joint has the following ligaments.
1. **Capsular ligament**: This is thick in front and thin behind.
2. **Palmar ligament**: This is a strong fibrocartilaginous plate which replaces the anterior part of the capsule. It is more firmly attached to the phalanx than to the metacarpal. The various palmar ligaments of the metacarpophalangeal joints are joined to one another by the deep transverse metacarpal ligament.
3. **Medial and lateral collateral ligaments**: These are oblique bands placed at the sides of the joint. Each runs downwards and forwards from the head of the metacarpal bone to the base of the phalanx. These are taut in flexion and relaxed in extension.

Movements at First Joint and Muscles Producing them
1. Flexion: Flexor pollicis longus and brevis
2. Extension: Extensor pollicis longus and brevis
3. Abduction: Abductor pollicis brevis
4. Adduction: Adductor pollicis

Movements at Second to Fifth Joints and Muscles Producing them
1. Flexion: Interossei and lumbricals.
2. Extension: Extensors of the fingers (Fig. 10.15).
3. Abduction: Dorsal interossei.
5. Circumduction: Above muscles in sequence.

**INTERPHALANGEAL JOINTS**  
**(PROXIMAL AND DISTAL)**

**Type**

Hinge variety of synovial joints (Fig. 10.18).

**Ligaments**

Similar to the metacarpophalangeal joints, that is one palmar fibrocartilaginous ligament and two collateral bands running downwards and forwards.
Movements at Interphalangeal Joint of the Thumb

Flexion: Flexor pollicis longus
Extension: Extensor pollicis longus.

Movements at Second to Fifth Digits

1. **Flexion.** Flexor digitorum superficialis at the proximal interphalangeal joint, and the flexor digitorum profundus at the distal joint (Fig. 10.19).
2. **Extension.** Interossei and lumbricals.

Segmental innervation of Movements of Upper UlfH

Figure 10.20 shows the segments of the spinal cord responsible for movements of the various joints of the upper limb.

Additional Reading

Surface marking is the projection of the deeper structures on the surface. Its importance lies in various medical and surgical procedures.

Bones cast a shadow in the radiographs, which can be examined carefully to detect age of the person, dislocation, fracture, and asymmetry between the two sides.

Sympathetic innervation of the blood vessels is important. After all the blood in the body is limited, and it has to perform diverse functions from 'head to toe'. Sympathetic nerves do manage to regulate the blood flow.

Limbs develop as appendages to the trunk. Emancipated upper limb's development is slightly faster than the weight-bearing lower limb.

Comparison of upper and lower limbs is quite interesting, as these were developed on a similar plan. Because of orthograde and plantigrade posture in man there are modifications to suit these necessities.

SURFACE MARKING

SURFACE LANDMARKS

The bony landmarks seen in different regions of the upper limb have been described in appropriate sections.
The surface marking of important structures is given in this chapter.
Axillary Artery

Hold the arm at right angles to the trunk with the palm directed upwards. The artery is then marked as a straight line by joining the following two points.

(i) Midpoint of the clavicle.
(ii) The second point at the junction of the anterior 1/3 and posterior 2/3 of the lateral wall of axilla at its lower limit where the arterial pulsations can be felt (Fig. 4.12).

At its termination the axillary artery, along with the accompanying nerves, forms a prominence which lies behind another projection caused by the biceps and coracobrachialis.

Brachial Artery

Brachial artery is marked by joining the following two points.

(i) A point at the junction of the anterior 1/3 and posterior 2/3 of the lateral wall of the axilla at its lower limit. Here the axillary artery ends and the brachial artery begins.
(ii) The second point, at the level of the neck of the radius medial to the tendons of the biceps brachii (Fig. 8.7).

Thus the artery begins on the medial side of the upper part of the arm, and runs downwards and slightly laterally to end in front of the elbow. At its termination it bifurcates into the radial and ulnar arteries.
Radial Artery

In the Forearm
Radial artery is marked by joining the following points. (i) A point in front of the elbow at the level of the neck of the radius medial to the tendons of the biceps brachii. (ii) The second point at the wrist between the anterior border of the radius laterally and the tendon of the flexor carpi radialis medially, where the radial pulse is commonly felt (Fig. 9.11). Its course is curved with a gentle convexity to the lateral side.

In the Hand
Radial artery is marked by joining the following three points.
(i) A point at the wrist between the anterior border of the radius and the tendon of the flexor carpi radialis. (ii) A second points just below the tip of the styloid process of the radius (Fig. 9.48). (iii) The third point at the proximal end of the first intermetacarpal space. In this part of its course, the artery runs obliquely downwards and backwards deep to the tendons of the abductor pollicis longus, the extensor pollicis brevis, and superficial to the lateral ligament of the wrist joint. Thus it passes through the anatomical snuff box to reach the proximal end of the first interosseous space.

Ulnar Artery
Ulnar artery is marked by joining the following three points.
(i) A point in front of the elbow at the level of the neck of the radius medial to the tendon of the biceps brachii (Figs 9.11, 9.13). (ii) A second point at the junction of the upper 1/3 and lower 2/3 of the medial border of the forearm (lateral to the ulnar nerve). (iii) The third point lateral to the pisiform bone. Thus the course of the ulnar artery is oblique in its upper 1/3, and vertical in its lower 2/3. The ulnar nerve lies just medial to the ulnar artery in the lower 2/3 of its course. The ulnar artery continues in the palm as the superficial palmar arch.

Superficial Palmar Arch
Superficial palmar arch is formed by the direct continuation of the ulnar artery, and is marked as a curved line by joining the following points.

(i) A point just lateral and distal to the pisiform bone (Fig. 9.30). (ii) The second point on the hook of the hamate bone, (iii) The third point on the distal border of the thenar eminence in line with the cleft between the index and middle fingers. The convexity of the arch is directed towards the fingers, and its most distal point is situated at the j level of the distal border of the fully extended thumb.

Deep Palmar Arch
Deep palmar arch is formed as the direct continuation of the radial artery. It has a slight convexity towards the fingers. It is marked by a more or less horizontal line, 4 cm (F/2") long, just distal to the hook of the hamate bone (Fig. 9.30).

The deep palmar arch lies 1.2 cm \( \frac{1}{4} \) proximal to the superficial palmar arch across the metacarpals, immediately distal to their bases. The deep branch of ulnar nerve lies in its concavity.

THE NERVES

Axillary Nerve with its Divisions
Axillary nerve with its divisions is marked as a horizontal line on the deltoid muscle, 2 cm above the midpoint between the tip of the acromion process and the insertion of the deltoid (Fig. 8.21).

Intramuscular injections in the deltoid are given in the lower part of the muscle nearer to its insertion to avoid injury to the nerve and its accompanying vessels.

Musculocutaneous Nerve
Musculocutaneous nerve is marked by joining the following two points.
(i) A point lateral to the axillary artery 3 err above its termination (Fig. 8.7). (ii) A point lateral to the tendon of the biceps brachii muscle 2 cm above the bend of the elbow. (Here it pierces the deep fascia and continues as the lateral cutaneous nerve of the forearm).

Median Nerve

In the Arm
Mark the brachial artery. The nerve is then marked lateral to the artery in the upper half, and medial to the artery in the lower half of the arm. The nerve crosses the artery anteriorly in the middle of the arm (Fig. 8.7).
In the Forearm
Median nerve is marked by joining the following two points. (i) A point medial to the brachial artery at the bend of the elbow.
(ii) A point in front of the wrist, over the tendon of the palmaris longus or 1 cm medial to the tendon of the flexor carpi radialis (Fig. 9.14).

In the Hand
Median nerve enters the palm by passing deep to flexor retinaculum, immediately below which it divides into lateral and medial branches. Lateral branch supplies the three muscles of thenar eminence and gives two branches to the thumb, and one to lateral side of index finger. Medial branch gives branches for the adjacent sides of index, middle and ring fingers. The lateral three and a half nail beds are also supplied (Fig. 9.21).

Radial Nerve

In the Arm
Radial nerve is marked by joining the following points. (i) The first point is at the junction of the anterior 1/3 and posterior 2/3 of the lateral wall of the axilla at its lower limit (Fig. 4.12). (ii) The second point is at the junction of the upper upper 1/3 and lower 2/3 of a line joining the lateral epicondyle with the insertion of the deltoid (Fig. 8.21). (iii) The third point is on the front of the elbow at the level of the lateral epicondyle 1 cm lateral to the tendon of the biceps brachii (Fig. 9.14). The first and second points are joined across the back of the arm to mark the oblique course of the radial nerve in the radial (spiral) groove (posterior compartment). The second and third points are joined on the front of the arm to mark the vertical course of the nerve in the anterior compartment.

In the Forearm
Superficial branch of radial nerve is marked by joining the following three points.
(i) A point 1 cm lateral to the biceps tendon at the level of the lateral epicondyle (Fig. 9.14).
(ii) The second point at the junction of the upper 2/3 and lower 1/3 of the lateral border of the forearm just lateral to the radial artery.
(iii) The third point at the anatomical snuff box. The nerve is vertical in its course between points one and two. At the second point it inclines backwards to reach the snuff box.

The nerve is closely related to the lateral side of the radial artery only in the middle 1/3 of the forearm.

Ulnar Nerve

In the Arm
Ulnar nerve is marked by joining the following points.
(i) A point at the junction of the anterior 1/3 and posterior 2/3 of the lateral wall of the axilla at its lower limit (lower border of the teres major muscle) (Fig. 8.7).
(ii) The second point at the middle of the medial border of the arm. (iii) The third point behind the base of the medial epicondyle of the humerus.

In the Forearm
Ulnar nerve is marked by joining the following two points.
(i) A point on the back of the base of the medial epicondyle of the humerus (Fig. 9.14).
(ii) The second point lateral to the pisiform bone. In the lower 2/3 of the forearm, the ulnar nerve lies medial to the ulnar artery.

In the Hand
Ulnar nerve lies superficial to the medial part of flexor retinaculum and medial to ulnar vessels where it divides into superficial and deep branches. The superficial branch supplies medial one and half digits including their nail beds. The deep branch passes backwards between pisiform and hook of hamate to lie in the concavity of the deep palmar arch (Fig. 9.21).

Posterior Interosseous Nerve or Deep Branch of Radial Nerve
It is marked by joining the following three points.
(a) A point 1 cm lateral to the biceps tendon at the level of the lateral epicondyle (Fig. 8.21).
(b) The second point at the junction of the upper 1/3 and lower 2/3 of a line joining the middle of the posterior aspect of the head of the radius to the dorsal tubercle at the lower end of the radius or Lister's tubercle (Fig. 9.48).
(c) The third point on the back of the wrist 1 cm medial to the dorsal tubercle.

THE JOINTS

Shoulder Joint
The anterior margin of the glenoid cavity corresponds to the lower half of the shoulder joint. It is marked by a line 3 cm long drawn downwards from a point just
lateral to the tip of the coracoid process. The line is slightly concave laterally.

Elbow Joint
The joint line is situated 2 cm below the line joining the two epicondyles, and slopes downwards and medially. This slope is responsible for the carrying angle.

Wrist Joint
The joint line is concave downwards, and is marked by joining the styloid processes of the radius and ulna.

RETINACULA

Flexor Retinaculum
Flexor retinaculum is marked by joining the following four points.
   (i) Pisiform bone (Fig. 9.18).
   (ii) Tubercle of the scaphoid bone.
   (iii) Hook of the hamate bone.
   (iv) Crest of the trapezium.
   The upper border is obtained by joining the first and second points, and the lower border by joining the third and fourth points. The upper border is concave upwards, and the lower border is concave downwards.

Extensor Retinaculum
Extensor retinaculum is an oblique band directed downwards and medially, and is about 2 cm broad (vertically). Laterally, it is attached to the lower salient part of the anterior border of the radius, and medially to the medial side of the carpus (pisiform and triquetral bones) and to the styloid process of the ulna (Fig. 9.43).

SYNOVIAL SHEATHS OF THE FLEXOR TENDONS

Common Flexor Synovial Sheath (Ulnar Bursa)
Above the flexor retinaculum (or lower transverse crease of the wrist) it extends into the forearm for about 2.5 cm. Here its medial border corresponds to the lateral edge of the tendon of the flexor carpi ulnaris, and its lateral border corresponds roughly to the tendon of the palmaris longus.

Ulnar bursa becomes narrower behind the flexor retinaculum, and broadens out below it.

Most of it terminates at the level of the upper transverse creases of the palm, but the medial part is continued up to the distal transverse crease of the little finger.

Synovial Sheaths for the Tendon of Flexor Pollicis Longus (Radial Bursa)
Radial bursa is a narrow tube which is coextensive with the ulnar bursa in the forearm and wrist. Below the flexor retinaculum it is continued into the thumb up to its distal crease.

Digital Synovial Sheaths
The synovial sheaths of the flexor tendons of the index, middle and ring fingers extend from the necks of the metacarpal bones (corresponding roughly to the lower transverse crease of the palm) to the bases of the terminal phalanges.

RADIOLOGICAL ANATOMY OF UPPER LIMB

General Remarks
In the case of the limbs plain radiography is mainly required. For complete information it is always advisable to have anteroposterior (AP) as well as lateral views; and as far as possible radiographs of the opposite limb should be available for comparison. The skeleton, owing to its high radiopacity, forms the most striking feature in plain skiagrams. In general the following information can be obtained from plain skiagrams of the limbs.

1. Fractures are seen as breaks in the surface continuity of the bone. A fracture line is usually irregular and asymmetrical. An epiphyseal line of an incompletely ossified bone, seen as a gap, should not be mistaken for a fracture: it has regular margins, and is bilaterally symmetrical. Supernumerary or accessory bones are also symmetrical.

2. Dislocations are seen as deranged or distorted relations between the articular bony surfaces forming a joint.

   1. Below the age of 25 years the age of a person can be determined from the knowledge of ossification of the bones.

   2. Certain deficiency diseases like rickets and scurvy can be diagnosed.

   3. Infections (osteomyelitis) and growths (osteoma, osteoclastoma, osteosarcoma, etc.) can be diagnosed. A localized rarefaction of a bone may indicate an infection.

   4. Congenital absence or fusion of bones can be seen.

Reading Plain Skiagrams of Limbs

1. Identify the view of the picture, anteroposterior (AP) or lateral. Each view shows a specific shape and arrangement of the bones.
2. Identify all the bones and their different parts visible in the given radiogram. Normal overlappings and 'end-on' appearances of bones in different views should be carefully studied.

3. Study the normal relations of the bones forming joints. The articular cartilage is radiolucent and does not cast any shadow. The radiological 'joint space' indicates the size of the articular cartilages. Normally the joint space is about 2-5 mm in adults.

4. Study the various epiphyses visible in young bones and try to determine the age of the person concerned.

**The Shoulder**

A. The following are seen in an AP view of the shoulder (Fig. 11.1A and B).

1. The upper end of the humerus, including the head, greater and lesser tuberosities and inferior tubercular sulcus.
1. The scapula, including the glenoid cavity, coracoid (seen end-on), acromion, the lateral, medial and superior borders, and the superior and inferior angles. The suprascapular notch may be seen.

2. The clavicle, except for its medial end.

3. Upper part of the thoracic cage, including the upper ribs.

B. Study the normal appearance of the following joints.

1. Shoulder Joint. The glenoid cavity articulates only with the lower half of the head of the humerus (when the arm is in the anatomical position). The upper part of the head lies beneath the acromion process. The greater tuberosity forms the lateral most bony point in the shoulder region.

2. Acromioclavicular joint.

C. Note the epiphyses if any, and determine the age with the help of ossifications described with individual bones.

The Elbow

A. Identify the following bones in an AP and lateral views of the elbow (Figs 11.2A and B, 11.3A and B).

The lower end of the humerus, including the medial and lateral epicondyles, the medial and lateral supracondylar ridges, the trochlea, the capitulum and the olecranon fossa.
2. The upper end of the ulna, including the olecranon and coronoid processes.

3. The upper end of the radius including its head, neck and tuberosity.

B. Study the normal appearance of the following joints in AP view.
   1. Elbow joint
   2. Superior radioulnar joint.
   C. Note the olecranon and coronoid processes in a lateral view of the elbow
   D. Note the epiphyses (if any) and determine the age with the help of ossifications described with individual bones.

The Hand

A. Identify the following bones in an AP skiagram (p. 114A and B)
   1. The lower end of the radius with its styloid
   2. The lower end of the ulna with its styloid
   3. The eight carpal bones. Note the overlapping of the triquetral and pisiform bones; and of the trapezium with the trapezoid. Also identify the tubercle of the scaphoid and the hook of the hamate,
   4. The five metacarpal bones.
Fig. 11.4A: Anteroposterior view of the hand.

Fig. 11.4B: Line drawing of Fig. 11.4A.
1. The fourteen phalanges.
2. The sesamoid bones present in relation to the thumb, and occasionally in relation to the other fingers.

B. Study the normal appearance of these joints.
1. The wrist joint.
2. The inferior radioulnar joint.
3. The intercarpal, carpometacarpal, metacarpophalangeal and interphalangeal joints.

C. Note the following bones in a lateral skiagram.
1. Lunate.
2. Scaphoid.
3. Capitate.
4. Trapezium.

D. Note the epiphyses and other incomplete ossifications, and determine the age with the help of ossifications described with individual bones.

**SYMPATHETIC INNERVATION**

1. Sympathetic nerves for the upper limb are derived from spinal segments T2 to T6. Most of the vasoconstrictor fibres supplying the arteries emerge from the segments T2 and T3. The preganglionic fibres arise from lateral horn cells and emerge from the spinal cord through ventral nerve roots. Passing through white rami communicans they reach the sympathetic chain. They ascend within the chain and end mostly in the cervicothoracic (stellate) ganglion.

2. Postganglionic fibres arise in the cervicothoracic ganglion. They pass through grey rami communicans to reach the nerve roots forming the brachial plexus.

3. The arteries of skeletal muscles are dilated by sympathetic activity. For the skin, however, these nerves are vasomotor, sudomotor and pilomotor.

4. Sympathetic denervation of the upper limb is done in conditions of vascular spasm Raynaud's disease, or in organic arterial disease where spasm is also present. Arteries of the upper limb can be denervated surgically by cutting the sympathetic chain below the third thoracic ganglion, severing the rami communicans connected with the second and third thoracic ganglia, or cutting intradurally the ventral roots of the second and third thoracic spinal nerves. The white ramus to the cervicothoracic ganglion is not cut, partly because its distribution to the upper limb is negligible, but mainly because this avoids Horner's syndrome.
THE UPPER LIMB

1. The upper limb bud appears on the ventrolateral aspect of body wall opposite the lower cervical segments at the end of the fourth week of embryonic life. The development of the upper limb precedes that of the lower limb by a few days.
2. Most investigators believe that the muscles of the upper limb develop *in situ* from the local mesoderm, and do not receive any contribution from the somites.
3. Early in the seventh week the upper limb bud rotates laterally through 90 degrees along its longitudinal axis so that the preaxial (radial) border faces laterally.
4. The axial artery of the upper limb develops from the seventh cervical intersegmental artery. In adults it persists as the axillary, brachial, anterior interosseous arteries and as deep palmar arch. The other arteries of the limb are secondary outgrowths from the axial artery.

DEVELOPMENT OF SKIN, MUSCLES, VERTEBRAE AND RIBS

By third week of intrauterine life, the para-axial mesoderm on either side of notochord gets segmented to form somites. Each somite gets divided into two parts — dermomyotome and sclerotome.

Dermomyotome forms dermis of skin and its myotome component gets divided into epimere and hypomere. Epimere forms the muscles innervated by dorsal primary rami, while hypomere forms the muscles innervated by ventral primary rami.

Muscles of head and neck are branchial in origin. Muscles of back develop from epimere, muscles of trunk or body develop from hypomere, muscles of limb develop *in situ*.

**Skin:** Epidermis, hair follicles, sweat and sebaceous glands develop from ectoderm; dermis is formed from dermomyotome.

**Sclerotome:** Cells of sclerotome proliferate: i. Ventrolaterally, to form transverse processes of vertebra. In the thoracic region, its costal element portion enlarges to form the ribs;

ii. Dorsally, to surround the spinal cord and forms the pedicles, laminae and spine;

iii. Ventromedially, to surround the notochord.

The segments are separated by intersegmental mesenchyme. Each segment is subdivided into a cranial and a caudal part, separated by loose mesenchyme.
Soon the caudal part of one segment fuses with the cranial part of adjacent lower segment including intersegmental mesenchyme to form the vertebral body.

Loose mesenchyme between cranial and caudal parts of the segments form the intervertebral disc (IVD). The notochord regresses from the region of the vertebral body, while it persists in the region of intervertebral disc to form the nucleus pulposus, which forms the central part of IVD. Its peripheral part is formed by the annulus fibrosus. Nucleus pulposus may herniate posteriorly to press on the spinal nerve roots. The condition is called the 'slipped disc'.

### COMPARISON OF UPPER LIMB AND LOWER LIMB

</tbody>
</table>
**Upper Limb**

**Muscles**
- Palmaris longus
- Flexor digitorum profundus
- Flexor pollicis longus
- Flexor digitorum superficialis
- Flexor carpi ulnaris
- Flexor carpi radialis
- Abductor pollicis longus
- Extensor digitorum
- Extensor pollicis longus

Anterior aspect: Flexors of wrist and digits and pronators of forearm
Posterior aspect: Extensors of wrist and digits and supinator.

**Nerves**
- Median nerve for 6V2 muscles and ulnar nerve for 1 1/2 muscles of anterior aspect of forearm. These are flexors of wrist and pronators of forearm. Posterior interosseous nerve or deep branch of radial supplies the extensors of the wrist and the supinator muscles of forearm. It winds around radius (preaxial bone) and corresponds to deep peroneal nerve. The superficial branch of radial nerve corresponds to the superficial peroneal nerve.

**Arteries**
- Brachial divides into radial and ulnar branches in the cubital fossa. Radial corresponds to anterior tibial artery.

**Hand**
- There are 8 small carpal bones occupying very small area of the hand. First carpometacarpal joint, i.e. joint between trapezium and base of 1st metacarpal is a unique joint. It is of saddle variety and permits a versatile movement of opposition in addition to other movements. This permits the hand to hold things, e.g. doll, pencil, food, bat, etc. Opponens pollicis is specially for opposition.

**Nerves**
- Median nerve supplies 5 muscles of hand including 1st and 2nd lumbricals (abductor pollicis brevis, flexor pollicis brevis, opponens pollicis, 1st and 2nd lumbricals).
- Ulnar nerve corresponds to lateral plantar nerve and supplies 15 intrinsic muscles of the hand.

**Muscles**
- Muscles which enter the palm from forearm, e.g. flexor digitorum superficialis, flexor digitorum profundus, flexor pollicis longus are supplied by the nerves of the forearm. 1st and 2nd lumbricals are unipennate and are supplied by median nerve. 3rd and 4th are bipennate being supplied by deep branch of ulnar nerve.

**Bones and Joints**
- Flexor digitorum accessorius is distinct muscle to straighten the action of flexor digitorum longus tendons in line with the toes on which these act. Tibialis anterior and tibialis posterior and peroneus longus reach the sole for the movements of inversion (first two) and eversion (last one) respectively.

**Blood vessels**
- No muscle on dorsum of hand. Radial artery corresponds to anterior tibial while ulnar artery corresponds to posterior tibial artery. Ulnar artery divides into superficial and deep branches. There

---

**Lower Limb**

**Muscles**
- Plantaris
- Flexor digitorum longus
- Flexor hallucis longus
- Soleus and flexor digitorum brevis
- Gastrocnemius (medial head)
- Gastrocnemius (lateral head)
- Tibialis anterior
- Extensor digitorum longus
- Extensor hallucis longus

Anterior aspect: Dorsiflexors of ankle joint
Posterior aspect: Plantar flexors (flexors) of ankle joint.
Lateral aspect: Evertors of subtalar joint.

Tibial nerve for all the plantar flexors of the ankle joint. Common peroneal winds around neck of fibula (postaxial bone) and divides into superficial and deep branches. The deep peroneal supplies dorsiflexors (extensors) of the ankle joint. The superficial peroneal nerve supplies a separate lateral compartment of leg.

Popliteal divides into anterior tibial and posterior tibial in the popliteal fossa. Posterior tibial corresponds to ulnar artery.

**Foot**
- 7 big tarsal bones occupying half of the foot. There are special joints between talus, calcaneus and navicular, i.e. subtalar and talocalcaneonavicular joints. They permit the movements of inversion and eversion (raising the medial border/lateral border of the foot) for walking on the uneven surfaces. This movement of inversion is similar to supination and of eversion to pronation of forearm. Flexor digitorum accessorius is distinct muscle to straighten the action of flexor digitorum longus tendons in line with the toes on which these act. Tibialis anterior and tibialis posterior and peroneus longus reach the sole for the movements of inversion (first two) and eversion (last one) respectively.

Medial plantar supplies four muscles of the sole including 1st lumbrical (abductor hallucis, flexor hallucis brevis, flexor digitorum brevis, 1st lumbrical).
Lateral plantar corresponds to ulnar nerve and supplies 14 intrinsic muscles of the sole.

Muscles which enter the sole from the leg, e.g. flexor digitorum longus, flexor hallucis longus, tibialis posterior, peroneus longus are supplied by the nerves of the leg. 1st lumbrical is unipennate and is supplied by medial plantar, 2nd-4th are bipennate being supplied by deep branch of lateral plantar nerve.

Extensor digitorum brevis present on dorsum of foot. Posterior tibial artery divides into medial plantar and lateral plantar branches. There is only one arch, the plantar arch formed by lateral plantar and dorsalis

Since nerves are the most important and precious component of our body, this appendix has been dedicated to the nerves of the upper limb. Most of the nerves course through different regions of the upper limb and have been described in parts in the respective regions. In this appendix, the course of the entire nerve from origin to its termination including the branches and clinical aspects has been described briefly.

A brief account of histological features of skin, skeletal muscle, cartilage, bone, blood vessel, peripheral nerve, and ganglia has also been included.

Five sample clinicoanatomical problems have been given to get an insight into the patient's problems. In addition, twenty sample multiple choice questions (MCQs) have been put here, for revision of the subject studied.

NERVES OF THE UPPER LIMB

BRACHIAL PLEXUS

Brachial plexus is the plexus formed by ventral rami of C5,6,7,8 and T1 nerves (Fig. 4.7). These rami or roots unite, divide, unite again and divide so that most of the muscles get nerve supply more than one root. Also each branch of brachial plexus gets formed by one, two, three or more roots/rami. So, damage to one root will not cause paralysis of one muscle. These nerve roots carry motor, sensory and sympathetic fibres to the skin and muscles supplied by them. The nerve roots receive sympathetic fibres from middle and inferior cervical and first thoracic ganglia.

A. Five Ventral Rami C5, C6, C7, C8 and T1 form Brachial Plexus

Branches from Rami

1. Dorsal scapular or nerve to rhomboideus is given off from C5 for rhomboideus major and rhomboideus minor, responsible for retraction of the scapula.
2. Long thoracic from C 6, 7, 8 for serratus anterior. Paralysis of the nerve leads to 'winging of scapula' when protraction is attempted (Fig. 4.10).

<table>
<thead>
<tr>
<th>Branches of Upper Trunk</th>
</tr>
</thead>
<tbody>
<tr>
<td>B. Ventral Rami of C5 and C7 Join to form Upper Trunk; Ventral Rami of C8 and T1 Join to form Lower Trunk</td>
</tr>
</tbody>
</table>

C. Each Trunk Divides into Dorsal and Ventral Divisions

Thus there are three ventral divisions for ventral aspect and three dorsal divisions for dorsal aspect of the limb.

D & E. Cords and their Branches

Ventral divisions of upper and middle trunks join to form lateral cord.

Branches of Lateral Cord

1. Lateral pectoral nerve for pectoralis major and minor.
2. Musculocutaneous nerve for coracobrachialis, two heads of biceps brachii and brachialis.
3. Lateral root of median nerve joins with its medial root to form median nerve.

Ventral Division of Lower Trunk Remains Single and forms Medial Cord

Branches of Medial Cord:

1. Medial pectoral nerve for pectoralis major and minor.
2. Medial cutaneous nerve of arm.
3. Medial cutaneous nerve of forearm.
1. Medial root of median joins with the lateral root to form median nerve for six and a half muscles of forearm and five muscles of lateral side of palm.
2. Ulnar nerve supplies one and a half muscles of forearm and 15 intrinsic muscles of palm.

**Posterior Cord**
Dorsal divisions of upper, middle and lower trunks join together to form **posterior cord**.

**Branches of Posterior Cord:**
1. Upper subscapular for subscapularis, a multi-pennate muscle.
2. Thoracodorsal nerve for latissimus dorsi.
3. Lower subscapular for subscapularis and teres major.
4. Axillary nerve for deltoid and skin over the lower half of deltoid and teres minor.
5. Radial nerve for extensors of elbow, wrist, metacarpophalangeal joints and supinator.

Thus a total of 17 branches are given off from the plexus, including 2 from roots, 2 from trunks and 13 from cords.

**Erb's Paralysis**
Erb's point is the segment where C5 and C6 roots join to form upper trunk, supracapsular and nerve to subclavius are given and ventral and dorsal divisions of upper trunk start (Fig. 4.8). In injury to this point, the abductors and lateral rotators of shoulder, flexors of elbow and supinators are paralysed. Arm hangs by the side. It is rotated medially extended at elbow joint, pronated at forearm, cutaneous loss on lateral side of arm and forearm, for example a policeman taking a tip (Fig. 4.9).

**Klumpke's Paralysis**
Damage to C8 and T1 segments is called Klumpke's paralysis. Small intrinsic muscles of hand are affected. It leads to 'complete claw hand', i.e. extension of metacarpophalangeal joints and flexion of interphalangeal joints, loss of sensation on medial side of forearm. If T1 is injured proximal to the white ramus communicans to first thoracic sympathetic ganglion, there is an associated Horner's syndrome. This is characterised by miosis or narrow pupil, partial ptosis or drooping of eyelid, enophthalmos or eye pushed inside the bony orbit and anhidrosis or absence of sweating on the side of lesion.

**Musculocutaneous Nerve**
Musculocutaneous nerve is so named as it supplies I muscles of front of arm and skin of lateral side of forearm.***)

---

**Root value** Ventral rami of C5, 6 and 7 segments I of spinal cord.

**Course**
Musculocutaneous nerve is a branch of the lateral cord of brachial plexus (Fig. 8.8), lies lateral to axillary and upper part of brachial artery. It supplies coracobrachialis pierces the muscle to lie in intermuscular septum between biceps brachii ai brachialis muscles, both of which are supplied by this nerve. At the crease of elbow it becomes cutaneous. The nerve is called the lateral cutaneous nerve of forearm which supplies skin of lateral side of forearm both on the front and back.

**Branches**
- **Muscular**: Coracobrachialis, long head of biceps brachii, short head of biceps brachii, I and brachialis.
- **Cutaneous**: Lateral side of forearm both on the front and the back.
- **Articular**: Elbow joint.

**AXILLARY OR CIRCUMFLEX NERVE**

Axillary or circumflex nerve is called axillary as it runs through the upper part of axilla though it does not supply any structure there. It used to be called circumflex as it goes round the surgical neck of humerus (Figs 7.6, 8.12, 8.24).

**Root value** Ventral rami of C5, 6 segments of spinal cord.

**Course**
Axillary or circumflex nerve is the smaller terminal branch of posterior cord (Fig. 4.7). It passes backwards through the quadrangular space (bounded by subscapularis above, teres major below, long head of triceps brachii medially and surgical neck of humerus laterally) (Fig. 7.11). Here it lies below the capsule of the shoulder joint. As it is about to pass behind the surgical neck of humerus it divides into an anterior and posterior divisions. Their branches are:

**Branches of Axillary (or Circumflex) Nerve**
The branches of axillary nerve are presented in Table ALL.

</tr>
<tr>
<td>Articular</td>
<td>Shoulder joint</td>
<td></td>
</tr>
</tbody>
</table>

### CLINICAL ANATOMY

Injury to axillary/circumflex nerve causes paralysis of deltoïd muscle. There is flattening of the shoulder region.

**Motor loss:** Paralysis of deltoïd muscle. Active movement of abduction of shoulder from 15° - 90° is not possible.

**Sensory loss:** Loss of sensation over lower half of deltoïd muscle.

### RADIAL NERVE

Radial nerve is the thickest branch of brachial plexus. **Root value** Ventral rami of C5-C8, T1 segments of spinal cord (Fig. 4.7).

**Course**

**Axilla:** Radial nerve lies against the muscles forming the posterior wall of axilla, i.e. subscapularis, teres major and latissimus dorsi. It then lies in the lower triangular space between teres major, long head of triceps brachii and shaft of humerus. It gives two muscular and one cutaneous branch in the axilla (Fig. 8.24).

**Radial Sulcus:** Radial nerve enters through the lower triangular space into the radial sulcus, where it lies between the long and medial heads of triceps brachii along with profunda brachii vessels (Fig. 8.10). Long and lateral heads form the roof of the radial sulcus. It leaves the sulcus by piercing the lateral intermuscular septum. In the sulcus, it gives three muscular and two cutaneous branches (Fig. 8.12).

**Front of Arm:** Radial nerve enters the lower lateral part of arm and lies between brachialis on the medial side and brachioradialis with extensor carpi radialis longus on the lateral side. It supplies the latter two muscles and also brachialis (lateral part). The nerve descends deep in this interval to reach the lateral epicondyle, where it ends by dividing into its two terminal branches—the superficial and deep or posterior interosseous branches (Figs 8.16, 9.14).

**Posterior interosseous branch:** Lies in the lateral part of cubital fossa, where it supplies extensor carpi radialis brevis and supinator muscles. Then it enters into the back of forearm by passing through supinator muscle. There the nerve supplies abductor pollicis longus, extensor pollicis brevis, extensor pollicis longus, extensor digitorum, extensor indicis, extensor digiti minimi and extensor carpi ulnaris. It ends in a pseudoganglion branches of which supply the wrist joint (Fig. 9.50).

**Superficial branch:** Is given off in the cubital fossa and runs on the lateral side of forearm accompanied by radial artery in the upper two-thirds of forearm (Fig. 9.13). Then it bends posteriorly to supply the lateral half of dorsum of hand and lateral two and a half digits till distal interphalangeal joints. Its branches cross over the anatomical snuff box (Fig. 9.31).

### Branches of Radial Nerve

The branches of radial nerve are presented in Table Al.2.

### CLINICAL ANATOMY

Radial nerve may be injured in radial groove during fracture of humerus of that region. It may also be damaged by improper use of the crutch, or 'Saturday night palsy.' If it is injured in axilla there is complete loss of active extension of elbow joint as all branches to triceps get paralysed. In addition, it will lead to wrist drop (Fig. 9.47).

If it is injured in the radial sulcus, there is weakness of elbow extension with wrist drop. If it is injured at level of lateral epicondyle, the extension of elbow is normal but there is wrist drop.

Wrtet - Arog, TM'sams, inafoyifj ti extejad the. wrist and metacarpophalangeal joints. The joints of fingers can be extended by interossei and

In Palm: Median nerve lies medial to the muscles of thenar eminence, which it supplies. It also gives cutaneous branches to lateral three and a half digits and their nail beds and skin of distal phalanges on dorsum (Fig. 2.31).

Branches of Median Nerve

The branches of median nerve are presented in Table A1.3.

CLINICAL ANATOMY

Usually median nerve is injured above the elbow. If it is injured, muscles supplied by it in cubital fossa, forearm and hand are paralysed.

Motor loss: Four and a half flexors of forearm and two pronators of forearm leading to 'pointing index finger'; of thenar eminence muscles and 1st and 2nd lumbricals. These muscles are responsible for the gross movements of fingers. So, it is called labourer's nerve.

Cutaneous loss: Lateral two-thirds of palm, loss of sensation on lateral three and a half digits including dorsum of distal phalanges.

Articular loss: Joints of lateral three digits.

Vasomotor changes: Oedema, pigmentation of skin, nails get friable and dryness of skin.

Trophic changes: Flattening of forearm muscles except the medial side. Flattening of thenar eminence leading to ape-like hand. Ulcers on the tips of lateral three and a half digits.

Carpal Tunnel Syndrome

Carpal tunnel syndrome is the commonest condition affecting this nerve. There is flattening...

| Two digital branches to thumb, one to lateral side of index finger. |
| Two to adjacent sides of index and middle fingers, two to adjacent sides middle and ring fingers. These branches also supply dorsal aspects of distal phalanges of lateral three and a half digits. |

There it lies on medial part of flexor digitorum profundus. It gets the company of ulnar artery in lower two-thirds of forearm (Fig. 9.13). It gives two muscular and two cutaneous branches. Finally it lies to the medial part of flexor retinaculum to enter palm. At the distal border of retinaculum the nerve divides into its superficial and deep branches (Figs 9.32, 9.33).

**Palm:** Superficial branch supplies palmaris brevis and digital branches to medial one and a half digits. Deep branch supplies most of the intrinsic muscles of the hand. At first it supplies three muscles of hypothenar eminence, running in the concavity of deep palmar arch it gives branches to 4th and 3rd lumbricals, 4,3,2,1 dorsal interossei and 4,3,2,1 palmar interossei to end in adductor pollicis. Since it supplies intrinsic muscles of hand responsible for finer movements, this nerve is called 'musicians nerve' (Fig 9.21).

### Branches of the Ulnar Nerve

The branches of ulnar nerve are presented in Table A1.4.

### CLINICAL ANATOMY

Ulnar nerve is mostly injured at the wrist. It leads to motor loss of the muscles of palm mentioned above; sensory loss in the medial one and a half digits including nail beds, dorsum of distal phalanges.

</table>

*Vasomotor changes:* Oedema, dry pigmented skin, friable nails.

*Trophic changes:* Loss of hypothenar eminence, prominence of metacarpal bones due to paralysis of interossei. Palm shows 'guttering' between the metacarpals.

*Position:* Partial clawing of hand with hyper-extension of metacarpophalangeal and flexion of interphalangeal joints. The clawing is less in index and middle fingers.

If ulnar nerve is injured at the elbow, the clawing of the fingers is less, because medial half of flexor digitorum profundus (flexor of proximal and distal interphalangeal joints) also gets paralysed. It is called 'action of paradox'.

If both ulnar and median nerves gets paralysed, there is complete claw-hand.

**HISTOLOGICAL FEATURES**

**Skin**

Skin is the outer garment of the body. It is of two types: thick skin found in palm/sole, and thin of hairy skin over the rest of the body. Histologically it is composed of: external layer the epidermis and ar inner layer, the dermis. The epithelium of epidermis is stratified squamous keratinised type, and comprises: (i) stratum basale, (ii) stratum spinosum (thick layer), (iii) stratum granulosum, (iv) stratum lucidum, and (v) stratum corneum. Dermis consists of outer papillary layer and inner or deeper reticulai layer. It contains capillaries, nerve endings, ducts of sweat glands and hair follicle.

Appendages of skin are nail, hair, sebaceous glands arrector pili muscles and sweat glands.

**Skeletal muscle:** It is the most abundant type of muscle comprises about 40% of the body weight. The I muscle is surrounded all over by epimysium. Each muscle fasciculus is surrounded by perimysium and each fibre is covered by endomysium. Each muscle fibre or cell is a multinucleated cylinder, with alternate dark and light bands and peripheral multiple nuclei. These fibres are not attached to each other by cell junctions. These fibres do not branch.

**Cartilage**

Cartilage is a specialised dense tissue. It is seen in the respiratory system, pinna, ends of bones forming the joint. Cartilage is surrounded on outside by perichondrium, consisting of outer fibrous and inner vascular and chondrogenic layer. The cartilage is classified into three types: hyaline, elastic and fibrocartilage. Hyaline cartilage is found in nose, trachea, lungs. Chondrocytes are seen in groups of 2 or 4. Matrix surrounds the cells, fibres are invisible.

Elastic cartilage is found in pinna, epiglottis and arytenoid cartilage. The cartilage cells are singly placed. The matrix shows many elastic fibres.

White fibrocartilage is found in menisci of knee joint, intra-articular disc and annulus fibrosus of intervertebral discs. The chondrocytes are fewer and are arranged parallel to the fibre bundles. The matrix contains numerous thick collagen bundles.

Growth in the cartilage occurs from the perichondrium - the appositional growth. It also grows from within, called the interstitial growth.

**Bone**

Histologically the bone is of two types: compact seen in the shaft of bone, and cancellous seen at the end of bone deep to thin layer of compact bone.
The bone on the external surface is surrounded by the periosteum, made of outer fibrous and inner cellular layer with osteogenic cells.

The bony tissue is seen as lamellae. In compact bone, these are arranged around the whole circumference of bone beneath the periosteum. These are called 'circumferential lamellae'. Lamellae arranged around the Haversian canal are called 'Haversian lamellae' and lamellae in between the Haversian lamellae are called 'interstitial lamellae'. Between these lamellae are spaces or lacunae which house the osteocytes. The lacunae are connected to Haversian canal and other lacunae by canaliculi. This type of bone contains more bony tissue and less spaces. In spongy/cancellous/trabecular bone, the lamellae form plates which surround larger spaces filled with bone marrow.

Bone only grows by apposition from the surface.

**Bloodvessels**

Arteries and veins constitute blood vessel. Both these are made of three layers. These are tunica intima, tunica media and tunica adventitia from within outwards. The differences lie in the proportion of these layers.

Artery - Tunica intima comprises the squamous inner lining. Tunica media forms two-thirds of arterial wall and comprises smooth muscle fibres and elastic fibres.

Tunica adventitia forms outer one-third and is composed of collagen fibres.

Vein - Tunica intima comprises the squamous lining. Tunica media forms one-third of thickness of wall and is composed of muscle fibres and collagen fibres. Tunica adventitia forms two-thirds of thickness of the wall, formed chiefly of collagen fibres. The lumen of vein is mostly visible with red blood cell in it.

**Peripheral Nerve**

The whole nerve is covered by epineurium. The nerve bundles are covered by perineurium while each nerve fibre is surrounded by endoneurium. Deep to endoneurium lies the neurilemma forming the cell membrane of the process of neuron. Next to it is the thick myelin sheath with nodes. In the area of internode, Schwann cells are visible. Deep to myelin sheath is the single axon enclosed in the axolemma. Transverse section of nerve depicts axon, myelin and neurilemma.

**Ganglia**

Spinal ganglion or dorsal root ganglion shows collection of neurons and collection of nerve fibres in groups. Autonomic ganglion shows neurons and nerve fibres scattered.

---

**CLINICOANATOMICAL PROBLEMS**

1. A 50-year-old man fell off his bicycle. He heard a cracking noise and felt severe pain in his right shoulder region. He noted that the lateral part of the shoulder drooped and medial end of clavicle was elevated.

Clinicoanatomical problems:
- ?Which is the common site of fracture of clavicle and why?
- ?Why did his shoulder droop down?

Ans. The clavicle gets fractured at the junction of medial two-thirds and lateral one-third. This is the weak point as it lies at the junction of two opposing curvatures.

The shoulder drooped down, because of the weight of the unsupported shoulder.

2. A young man practicing tennis complained of severe pain over lateral part of his right elbow. The pain was pin pointed over his lateral epicondyle.

Clinicoanatomical problems:
- ?Why does pain occur over lateral epicondyle during tennis games?
- ?Which other games can cause similar pain?

Ans. The pain is due to lateral epicondylitis also called tennis elbow. This is due to repeated microtrauma to the common extensor origin of extensor muscles of the forearm. It can also occur in swimming, gymnastics, baseball, golf, i.e. any sport which involves strenuous use of the extensors of the forearm.

3. A 55-year-old woman complained of abnormal sensations in her right thumb, index, middle and part of ring fingers. Her pain increased during night. There was weakness of her thumb movements.

Clinicoanatomical problems:
- Which nerve was affected and where? Name the syndrome.

Ans. Median nerve is affected while it travels deep to the flexor retinaculum. The syndrome is ‘carpal tunnel syndrome’. There are abnormal sensation in lateral .three and a half digits, but there is no loss of sensation over lateral two-thirds of palm. The nerve supply of this area is from palmar cutaneous branch of median nerve which passes superficial to the flexor retinaculum.
4. A 70-year-old lady fell on her left forearm. She heard a crack in the wrist. There was swelling and a bend just proximal to wrist with lateral deviation of the hand.

**Clinicoanatomical problems:**
- Which forearm bone is fractured?
- Reason of bend just proximal to wrist?
- Which joint can be subluxated?

Ans. There is fracture of the distal end of radius. The backward bend just proximal to the wrist is due to the pull of extensor muscles on the distal segment of radius. The inferior radioulnar joint is usually subluxated.

5. A 45-year-old woman complained of a firm painless mass in the upper lateral quadrant of her left breast. The nipple was also raised. Axillary lymph nodes were palpable and firm. It was diagnosed as cancer breast.

**Clinicoanatomical problems:**
- Where does the lymph from upper lateral quadrant drain?
- What causes the elevation of the nipple.

Ans. The lymph from the upper lateral quadrant drains mainly into the pectoral group of axillary lymph nodes. The lymphatics also drain into supraclavicular and infraclavicular lymph nodes. Blockage of some lymph vessels by the cancer cells causes oedema of skin with dimpled appearance. This is called 'peau d'orange'. When cancer cells invade the suspensory ligaments, glandular tissue or the ducts, there is retraction of the nipple.

**MULTIPLE CHOICE QUESTIONS**

A. Select the best response:

1. The site of injury in Erb's paralysis is:
   - a. Upper trunk of brachial plexus
   - b. Lower trunk of brachial plexus
   - c. Anterior division of lower trunk
   - d. Posterior cord of brachial plexus

2. The lymphatics from the thumb and its web drain into the following group of axillary lymph nodes:
   - a. Anterior
   - b. Posterior
   - c. Central
   - d. Apical

3. The spinal segments which supply the small muscles of the hand are:
   - a. C5, C6
   - b. C6, C7
   - c. C7, C8
   - d. C8, T1

4. The carpal tunnel contains all the following structures except:
   - a. Median nerve
   - b. Ulnar nerve
   - c. Flexor pollicis longus tendon
   - d. Flexor digitorum superficialis tendons.

5. The bone which develops by intramembranous ossification is:
   - a. Humerus
   - b. Scapula
   - c. Clavicle
   - d. Pisiform

6. The nerve which lies behind the medial epicondyle of humerus is:
   - a. Musculocutaneous
   - b. Ulnar
   - c. Radial
   - d. Median

7. Which of the following muscle is the flexor of distal interphalangeal joint
   - a. Flexor digitorum superficialis
   - b. Flexor digitorum profundus
   - c. Lumbricals
   - d. Palmar interossei

8. The important structures in the cubital fossa from medial to lateral are:
   - a. Brachial artery, median nerve, tendon of biceps brachii and superficial branch of radial nerve
   - b. Median nerve, tendon of biceps brachii, brachial artery and superficial branch of radial nerve.
   - c. Median nerve, brachial artery, tendon of biceps brachii, superficial branch of radial nerve.
   - d. Median nerve, brachial artery, superficial branch of radial nerve and tendon of biceps brachii.

9. The most commonly used vein for blood sampling and intravenous injection is:
   - a. Basilic vein
   - b. Cephalic vein
   - c. Axillary vein
   - d. Median cubital vein
10. The supination and pronation movements of forearm take place at:
   a. Superior and inferior radioulnar joints.
   b. Elbow and superior radioulnar joints.
   c. Inferior radioulnar and wrist joints.
   d. Only superior radioulnar joint.

B. Match the following on the left side with their appropriate answers on the right side:

11. The nerve injury and the clinical signs:
   a. Radial nerve  i. Claw hand
   b. Median nerve  ii. Wrist drop
   c. Long thoracic nerve  iii. Ape thumb
   d. Ulnar nerve  iv. Winging of scapula

12. Tendon reflexes and segmental innervation:
   a. Triceps  i. C5, C6, C7
   b. Biceps brachii  ii. C5, C6
   c. Brachioradialis  iii. C6, C7, C8

13. Muscles and the movements at shoulder joints:
   a. Supraspinatus  i. Medial rotation
   b. Subscapularis  ii. Lateral rotation
   c. Latissimus dorsi  iii. Abduction
   d. Teres minor  iv. Extension

14. Muscles and their nerve supply:
   a. Deltoid  i. Ulnar
   b. Supinator  ii. Median
   c. 1st lumbrical  iii. Axillary
   d. Adductor pollicis  iv. Radial

15. Sensory innervation of skin:
   a. Palmar surface of ring and little finger  i. C3, C4
   b. Palmar surface of thumb and index finger  ii. C8
   c. Medial aspect of arm  iii. T1,T2
   d. Tip of the shoulder  iv. C6

C. For each of the incomplete statements or questions below, one or more completions or answers given is/are correct. Select.
   A. If only 1, 2 and 3 are correct
   B. If only 1 and 3 are correct
   C. If only 2 and 4 are correct
   D. If only 4 is correct
   E. If all are correct

16. Injury to the median nerve in the arm would affect
   1. Pronation of the forearm
   2. Flexion of the wrist
   3. Flexion of the thumb
   4. Supination of the forearm

17. Which of the following is/are true regarding humerus?
   1. The head of the humerus commonly dislocates posteriorly.
   2. Common sites of fracture are surgical neck, shaft and supracondylar region.
   3. Lower end is the growing end.
   4. Axillary, radial and ulnar nerves are directly related to the bone.

18. Clavicle
   1. Is a long bone
   2. Develops by intramembranous ossification
   3. Is the first bone to ossify
   4. Has a well-developed medullary cavity.

19. In Erb's paralysis.
   1. Abduction and lateral rotation of the arm are lost.
   2. Flexion and pronation of the forearm are lost
   3. Biceps and supinator jerks are lost
   4. Sensations are lost over the medial side of the arm.

20. Which of the following statements are true regarding 'mammary gland'.
   1. It is modified sweat gland
   2. Lies in superficial fascia
   3. 75% of the lymph from mammary gland drains into axillary lymph nodes.
   4. Some lymphatic vessels communicate with the lymph vessels of opposite side.

Introduction to the Thorax
The thorax forms the upper part of the trunk of the body. It permits boarding and lodging of not only the thoracic viscera, but also provides necessary shelter to some of the abdominal viscera.

The trunk of the body is divided by the diaphragm into an upper part, called the thorax, and a lower part, called the abdomen. The thorax is supported by a skeletal framework, thoracic cage. The thoracic cavity contains the principal organs of respiration - the lungs and of circulation - the heart, both of which are vital for life.

**THE SKELETON OF THE THORAX**

The skeleton of the thorax is also known as the thoracic cage. It is an osseocartilaginous, elastic cage which is primarily designed for increasing and decreasing the intrathoracic pressure, so that air is sucked into the lungs during inspiration and expelled during expiration.

**FORMATION**

*Anteriorly* by the sternum (Figs 12.1, 12.2).

*Posteriorly* by the 12 thoracic vertebrae and the intervening intervertebral discs (Fig. 12.3).

*On each side* by 12 ribs with their cartilages.

Each rib articulates posteriorly with the vertebral column. Anteriorly, only the upper seven ribs articulate with the sternum through their cartilages and these are called true or vertebrosternal ribs. The costal cartilages of the next three ribs, i.e. the eighth, ninth and tenth, end by joining the next higher costal cartilage. These ribs are, therefore, known as vertebrochondral ribs. The costal cartilages of the seventh, eighth, ninth and tenth ribs form the costal margin. The anterior ends of the eleventh and twelfth
ribs are free: these are called floating or vertebral ribs. The vertebrochondral and vertebral ribs, i.e. the last five ribs are also called false ribs because they do not articulate with the sternum.

The costovertebral, manubrio-asternal and chondrosternal joints permit movements of the thoracic cage during breathing.

**SHAPE**

The thorax resembles a truncated cone which is narrow above and broad below (Fig. 12.4). The narrow upper end is continuous with the root of the neck from which it is partly separated by the supraneural membrane or Sibson's fascia. The broad or lower end is almost completely separated from the abdomen by the diaphragm which is deeply concave downwards. The thoracic cavity is actually much smaller than what it appears to be because the narrow upper part appears broad due to the shoulders, and the lower part is greatly encroached upon by the abdominal cavity due to the upward convexity of the diaphragm.

In transverse section, the thorax is reniform (bean-shaped, or kidney-shaped). The transverse diameter is greater than the anteroposterior diameter. However, in infants below the age of two years, it is circular. In quadrupeds, the anteroposterior diameter is greater than the transverse, as shown in Fig. 12.5.

In infants, the ribs are horizontal and as a result the respiration is purely abdominal, by action of the diaphragm.

In adults, the thorax is oval. The ribs are oblique and their movements alternately increase and decrease the diameters of the thorax. This results in the drawing in of air into the thorax called inspiration and its expulsion is called expiration. This is called thoracic respiration. In the adult, we, therefore, have both abdominal and thoracic respiration.
Figs 12.1 to 12.3: Shape and construction of the thoracic cage as seen from the front (Fig. 12.1), from the lateral side (Fig. 12.2), and from behind (Fig. 12.3).

---

**CLINICAL ANATOMY**

1. The chest wall of the child is highly elastic, and fractures of the ribs are, therefore, rare. In adults, the ribs may be fractured by direct or indirect violence. In indirect violence, like crushing injury, the rib fractures at its weakest point located at the angle. The upper two ribs which are protected by the clavicle, and the lower two ribs which are free to swing are least commonly injured.

2. A cervical rib is a rib attached to vertebra C7. It occurs in about 0.5% of subjects. Such a rib may exert pressure on the lower trunk of the brachial plexus which arches over a cervical rib. Such a person complains paraesthesiae or abnormal sensations along the ulnar border of the forearm, supplied by segment T1. Vascular changes may occur.

3. In coarctation or narrowing of the aorta, the posterior intercostal arteries get enlarged greatly to provide a collateral circulation. Pressure of the enlarged arteries produces characteristic notching on the ribs.
The narrow upper end of the thorax, which is continuous with the neck, is called the inlet of the thorax (Fig. 12.6). It is kidney-shaped. Its transverse diameter is 10-12.5 cm. The anteroposterior diameter is about 5 cm.

**Boundaries**

**Anteriorly**: Upper border of the manubrium sterni.

**Posteriorly**: Superior surface of the body of the first thoracic vertebra.

**On each side**: First rib with its cartilage.

The plane of the inlet is directed downwards and forwards with an obliquity of about 45 degrees. The anterior part of the inlet lies 3.7 cm below the posterior part, so that the upper border of the manubrium sterni lies at the level of the upper border of the third thoracic vertebra.

**Diaphragm or Partition at the Inlet of the Thorax**

The diaphragm is in two halves, right and left, with a cleft in between. Each half is also known as Sibson's fascia or suprapleural membrane. It partly separates the thorax from the neck. The membrane is triangular in shape. Its apex is attached to the tip of the transverse process of the seventh cervical vertebra and the base to the inner border of the first rib and its cartilage. Morphologically it is regarded as the flattened tendon of the scalenus minimus (pleuralis) muscle. Functionally, it provides rigidity to the thoracic inlet, so that the root of the neck is not puffed up and down during respiration. The inferior surface of the membrane is fused to the cervical pleura, beneath which lies the apex of the lung. Its superior surface is related to the subclavian vessels and other structures at the root of the neck (Figs 12.7, 12.8).

**Structures Passing through the Inlet of Thorax**

**Viscera**

- Trachea, oesophagus, apices of the lungs with pleura, remains of the thymus. Figure 12.9 depicts the structures passing through the inlet of the thorax. **Large vessels**
  - Brachiocephalic artery on right side.
  - Left common carotid artery and the left subclavian artery on the left side. Right and left brachiocephalic veins. **Smaller vessels**
  - Right and left internal thoracic arteries.
  - Right and left superior intercostal arteries.
  - Right and left first posterior intercostal veins.
  - Inferior thyroid veins.

**Nerves**

- Right and left phrenic nerves.
- Right and left vagus nerves.
- Right and left sympathetic trunks.
- Right and left first thoracic nerves as they ascend across the first rib to join the brachial plexus. **Muscles**
  - Sternohyoid, sternothyroid and longus colli.
Fig. 12.7: Thoracic inlet showing cervical dome of the pleura on left side of body and its relationship to inner border
CLINICAL ANATOMY

Thoracic Inlet Syndrome: Two structures arch over the first rib: the subclavian artery and first thoracic nerve. These structures may be pulled or pressed by a cervical rib or by variations in the insertion of the scalenus anterior. The symptoms may, therefore, be vascular, neural, or both.

THE INFERIOR APERTURE/OUTLET OF THE THORAX

The inferior aperture is the broad end of the thorax which surrounds the upper part of the abdominal cavity, but is separated from it by the diaphragm.

Boundaries

Anteriorly: Infrasternal angle between the two costal margins.

Posteriorly: Inferior surface of the body of the twelfth thoracic vertebra.

On each side: (i) Costal margin formed by the cartilages of seventh to twelfth ribs.

Diaphragm at the Outlet of Thorax

The outlet is closed by a large musculotendinous partition, called the diaphragm—the thoracoabdo-
minal diaphragm—which separates the thorax from the abdomen.

It transmits: (i) the aorta, (ii) the thoracic duct, and (iii) the azygos vein.

**Structures passing through the diaphragm**

B. The oesophageal opening lies in the muscular part of the diaphragm at the level of the tenth thoracic vertebra. It transmits: (i) the oesophagus, (ii) the gastric (vagus) nerves, and (iii) the oesophageal branches of the left gastric artery, with some oesophageal veins that accompany the arteries.

**Large Openings in the Diaphragm**

A. The aortic opening is osseoaponeurotic. It lies at the level of the eighth thoracic vertebra. It transmits: (i) the inferior vena cava at the lower border of the twelfth thoracic vertebra, (ii) branches of the right phrenic nerve, and (iii) some oesophageal veins that accompany the arteries.

There are three large, and several small, openings in the diaphragm which allow passage to structures from thorax to abdomen or vice versa (Fig. 12.10).

**Fig. 12.9:** Structures passing through the inlet of the thorax.

**Fig. 12.10:** Structures passing through the diaphragm.
Small Openings in the Diaphragm

(a) Each crus of the diaphragm is pierced by the greater and lesser splanchnic nerves. The left crus is pierced in addition by the hemiazygos vein.

(b) The sympathetic chain passes from the thorax to the abdomen behind the medial arcuate ligament also called the medial lumbocostal arch.

(c) The subcostal nerve and vessels pass behind the lateral arcuate ligament or lateral lumbocostal arch.

(d) The superior epigastric vessels and some lymphatics pass between the xiphoid and costal (7th costal cartilage) origins of the diaphragm. This gap is known as Larry's space or foramen of Morgagni.

(e) The musculophrenic vessels pierce the diaphragm at the level of ninth costal cartilage.

(f) Several small veins pass through minute apertures in the central tendon.

SURFACE LANDMARKS OF THE THORAX

Bony Landmarks

1. Suprasternal or jugular notch (Fig. 12.11). It is felt just above the superior border of the manubrium between the sternal ends of the clavicles. It lies at the level of the lower border of the body of the second thoracic vertebra. The trachea can be palpated in this notch.

2. Sternal angle of Louis: It is felt as a transverse ridge about 5 cm below the suprasternal notch. It marks the manubriosternal joint, and lies at the level of the second costal cartilage anteriorly, and the disc between the fourth and fifth thoracic vertebrae posteriorly. This is an important landmark for the following reasons:

   i. The ribs are counted from this level downwards. There is no other reliable point (anteriorly) from which the ribs may be counted. The second costal cartilage and rib lie at the level of the sternal angle. The ribs are counted from here by tracing the finger downwards and laterally (because the lower costal cartilages are crowded and the anterior parts of the intercostal spaces are very narrow).

   ii. It marks the plane which separates the superior mediastinum from the inferior mediastinum.

   iii. The ascending aorta ends at this level.

   iv. The arch of the aorta begins and also ends at this level.

   v. The descending aorta begins at this level.

   vi. The trachea divides into two principal bronchi.

   vii. The azygos vein arches over the root of the right lung and opens into the superior vena cava.

   viii. The pulmonary trunk divides into two pulmonary arteries just below this level.

   ix. The thoracic duct crosses from the right to the left side at the level of the fifth thoracic vertebra and reaches the left side at the level of the sternal angle.

   x. It marks the upper limit of the base of the heart.

   xi. The cardiac plexuses are situated at the same level.

3. Xiphisternal joint. The costal margin on each side is formed by the seventh to tenth costal cartilages. Between the two costal margins there lies the infrasternal or subcostal angle. The depression in the angle is also known as the epigastric fossa.

   The xiphoid process lies in the floor of the epigastric fossa. At the apex of the angle the xiphisternal joint may be felt as a short transverse ridge. It lies at the level of the upper border of the ninth thoracic vertebra (Fig. 12.1).

4. Costal cartilages. The second costal cartilage is attached to the sternal angle. The seventh cartilage bounds the upper part of the infrasternal angle. The lateral border of the rectus abdominis or the linea semilunaris joins the costal margin at the tip of the
ninth costal cartilage, through which also passes the midclavicular plane. The tenth costal cartilage forms the lower part of the costal margin (Figs. 12.1, 12.2).

5. **Ribs.** The scapula overlies the second to seventh ribs on the posterolateral aspect of the chest wall. The tenth rib is the lowest point, lies at the level of the third lumbar vertebra. Though the eleventh rib is longer than the twelfth, both of them are confined to the back and are not seen from the front (Fig. 12.2).

6. **Thoracic vertebral spines.** The first prominent spine felt at the lower part of the back of the neck is that of the *seventh cervical vertebra or vertebra prominens*. Below this spine, all the thoracic spines can be palpated along the posterior median line (Fig. 12.3). The third thoracic spine lies at the level of the roots of the spines of the scapulae. The seventh thoracic spine lies at the level of the inferior angles of the scapulae.

### Soft Tissue Landmarks

1. **The nipple.** The position of the nipple varies considerably in females, but in males it usually lies in the fourth intercostal space about 10 cm from the midsternal line (Fig. 12.11).

2. **Apex beat.** It is a visible and palpable cardiac impulse in the left fifth intercostal space 9 cm from the midsternal line, or medial to the midclavicular plane.

3. **Trachea.** It is palpable in the suprasternal notch midway between the two clavicles.

4. **Midclavicular or lateral vertical or mammary plane.** It is a vertical plane passing through the midsignal point and the tip of the ninth costal cartilage (Fig. 15.9).

5. **Midaxillary line.** It passes vertically between the two folds of the axilla (Fig. 15.9).

6. **Scapular line.** It passes vertically along the inferior angle of the scapula.
The thorax is an osseocartilaginous cavity or cage for various viscera, providing them due support and protection. This cage is not static, but dynamic, as it moves at its various joints, increasing or decreasing the various diameters of the cavity for an extremely important process of respiration, which is life for all of us.

**BONES OF THE THORAX**

**THE RIBS OR COSTAE**

1. There are 12 ribs on each side forming the greater part of the thoracic skeleton. The number may be increased by development of a cervical or a lumbar rib; or the number may be reduced to 11 by the absence of the twelfth rib.
2. The ribs are bony arches arranged one below the other (Fig. 13.1). The gaps between the ribs are called intercostal spaces. The spaces are deeper in front than behind, and deeper between the upper than between the lower ribs.
3. The ribs are placed obliquely, the upper ribs being less oblique than the lower. The obliquity reaches its maximum at the ninth rib, and thereafter it gradually decreases to the twelfth rib.
4. The length of the ribs increases from the first to the seventh ribs, and then gradually decreases from the eighth to twelfth ribs.
5. The breadth of the ribs decreases from above downwards. In the upper ten ribs, the anterior ends are broader than the posterior ends.
6. The first 7 ribs which are connected through their cartilages to the sternum are called true ribs, or vertebrosternal ribs. The remaining five are false ribs. Out of these the cartilages of the eighth, ninth and tenth ribs are joined to the next higher cartilage and are known as vertebrochondral ribs. The anterior
ends of the eleventh and twelfth ribs are free and are called floating ribs or vertebral ribs.

7. The first two and last three ribs have special features, and are atypical ribs. The third to ninth ribs are typical ribs.

**Typical Ribs**

*Side determination*

1. The anterior end bears a concave depression. The posterior end bears a head, a neck and a tubercle.
2. The shaft is convex outwards and there is costal groove situated along the lower part of its inner surface, so that the lower border is thin and the upper border rounded.

*Fig. 13.1: A typical rib of the right side.*
Features of a Typical Rib

Each rib has two ends, anterior and posterior. Its shaft comprises upper and lower borders, and outer and inner surfaces.

The anterior end is oval and concave for articulation with its costal cartilage.

The posterior or vertebral end is made up of the following parts:

1. The head has two facets that are separated by a crest. The lower larger facet articulates with the body of the numerically corresponding vertebra while the upper smaller facet articulates with the next higher vertebra (Fig. 13.2).

2. The neck lies in front of the transverse process of its own vertebra, and has two surfaces; anterior and posterior and two borders; superior and inferior. The anterior surface of the neck is smooth. The posterior surface is rough. The superior border or crest of the neck is thin. The inferior border is rounded.

3. The tubercle is placed on the outer surface of the rib at the junction of the neck and shaft. Its medial part is articular and forms the costotransverse joint with the corresponding vertebra. The lateral part is non-articular.

The shaft is flattened so that it has two surfaces: outer and inner and two borders: upper and lower. The shaft is curved with its convexity outwards (Fig. 13.3). It is bent at the angle which is situated about 5 cm lateral to the tubercle. It is also twisted at the angle.

1. The outer surface. The angle is marked by an oblique line on the outer surface directed downwards and laterally.

2. The inner surface is smooth and covered by the pleura. This surface is marked by a ridge which is continuous behind with the lower border of the neck. The costal groove lies between this ridge and the inferior border. The costal groove contains the posterior intercostal vessels and intercostal nerve.

Attachments and Relations of a Typical Rib

1. The crest of the head provides attachment to the intra-articular ligament of the costovertebral joint.

2. Anteriorly, the head provides attachment to the radiate ligament (Fig. 13.4) and is related to the sympathetic chain and to the costal pleura.

3. Attachments to the neck:
   (i) The anterior surface is covered by costal pleura.
   (ii) The inferior costotransverse ligament is attached to the rough posterior surface (Fig. 13.5).
   (iii) The two laminae of the superior costotransverse ligament are attached to the crest of the neck (Fig. 13.6).

1. The lateral non-articular part of the tubercle gives attachment to the lateral costotransverse ligament.

2. Attachments on the shaft
   (i) The thoracolumbar fascia and the lateral fibres of the sacrospinalis muscle are attached.
at about the eighth week of intrauterine life; and (b) three secondary centres, one for the head and two for the tubercle, which appear at about sixteen years and unite with the rest of the bone at about 25 years.

**The First Rib**

**Identification**

1. It is the shortest, broadest and most curved rib.
2. The shaft is not twisted.
3. It is flattened from above downwards so that it has superior and inferior surfaces; and outer and inner borders.

**Side Determination**

1. The anterior end is larger, thicker and pitted. The posterior end is small and rounded.
2. The outer border is convex.
3. The upper surface of the shaft is crossed obliquely by two shallow grooves separated by a ridge. The ridge is enlarged at the inner border of the rib to form the scalene tubercle.

When the rib is placed on a horizontal plane, i.e. with the superior surface facing upwards, both the ends of the rib touch the surface.

**Features of the First Rib**

1. The **anterior end** is larger and thicker than that in the other ribs. It is continuous with the first costal cartilage.
2. The **posterior end** comprises the following:
   a. The **head** is small and rounded. It articulates with the body of first thoracic vertebra.
   b. The neck is rounded and directed laterally, upwards and backwards.
   c. The **tubercle** is large. It coincides with the angle of the rib. It articulates with the transverse process of first thoracic vertebra to form the costotransverse joint.
3. The **shaft (body)** has two surfaces: upper and lower and two borders: outer and inner.
   a. The **upper surface** is marked by two shallow grooves, separated near the inner border by the scalene tubercle.
   b. The **lower surface** is smooth and has no costal groove.
   c. The **outer border** is convex, thick behind and thin in front.
   d. The **inner border** is concave.

to the angle. Medial to the angle, the *levator costae* and the sacrospinalis are attached. About 5 cm from the anterior end there is an indistinct oblique line, known as the anterior angle, which separates the origins of the *external oblique* from *serratus anterior*; in case of fifth to eighth ribs. The anterior angle also separates the origin of external oblique from that of latissimus dorsi in case of ninth and tenth ribs.

(ii) The interna/intercosta/muscle arises from the floor of the costal groove. The *intercostalis intimus* arises from the middle two-fourths of the ridge above the groove. The *subcostalis* is attached to the inner surfaces of the lower ribs.

(iii) The external intercostal muscle is attached on the outer lip of the upper border, while the internal intercostal and intercostalis intimi are attached on the inner lip of the upper border.

**Ossification of a Typical Rib**

A typical rib ossifies in cartilage from: (a) one primary centre (for the shaft) which appears, near the angle,
Attachments and Relations of the First Rib

1. Anteriorly, the neck is related from medial to lateral side to: (i) the sympathetic chain, (ii) the first posterior intercostal vein, (iii) the intercostal artery, and (iv) the first thoracic nerve (Fig. 13.7).

2. Superiorly, the neck is related to: (i) the deep cervical vessels, and (ii) the eighth cervical nerve.

3. The anterior groove on the superior surface of the shaft lodges the subclavian vein, and the posterior groove lodges the subclavian artery and the lower trunk of the brachial plexus.

4. The structures attached to the upper surface of the shaft are:
   (i) the origin of the subclavius muscle at the anterior end;
   (ii) the attachment of the costoclavicular ligament at the anterior end behind the subclavius;
   (iii) the insertion of the scalenus anterior on the scalene tubercle; and
   (iv) the insertion of the scalenus medius on the elongated rough area behind the groove for the subclavian artery.

5. The lower surface of the shaft is covered by costal pleura and is related near its outer border to the small first intercostal nerve which is very small.

6. The outer border gives origin to: (i) the external intercostal muscle, and (ii) the upper part of the first digitation of the serratus anterior, just behind the groove for the subclavian artery. The thick portion of the outer border is covered by the scalenus posterior.

7. The inner border gives attachment to the suprapleural membrane.

8. The tubercle gives attachment to the lateral costotransverse ligament.

Ossification

The first rib ossifies from one primary centre for the shaft and only two secondary centres, one for the head and the other for the tubercle. Otherwise its ossification is similar to that of a typical rib.

The Second Rib

Features

The features of the second rib are as follows.

1. The length is twice that of the first rib.

2. The shaft is sharply curved, like that of the first rib.

3. The non-articular part of the tubercle is small.

4. The angle is slight and is situated close to the tubercle.

5. The shaft has no twist. The outer surface is convex and faces more upwards than outwards. Near its middle it is marked by a large rough tubercle. This tubercle is a unique feature of the second rib. The inner surface of the shaft is smooth and concave. It faces more downwards than inwards. There is a short costal groove on the posterior part of this surface.

   The posterior part of the upper border has distinct outer and inner lips. The part of the outer lip just in front of the angle is rough.

Attachments

1. The rough tubercle on the outer surface gives origin to one and a half digitations of the serratus anterior muscle.

2. The rough part of the upper border receives the insertion of the scalenus posterior.

The Tenth Rib

The tenth rib closely resembles a typical rib, but is (i) shorter and (ii) has only a single facet on the head, for the body of the tenth thoracic vertebra.

The Eleventh and Twelfth Ribs

Eleventh and twelfth ribs are short. They have pointed ends. The necks and tubercles are absent. The angle and costal groove are poorly marked in the eleventh rib; and are absent in the twelfth rib.

Attachment and Relations of the Twelfth Rib

1. The capsular and radiate ligaments are attached to the head of the rib.
2. The following are attached on the inner surface:
   (i) The quadratus lumborum is inserted into the lower part of the medial half to two-thirds of this surface (Fig. 13.8A). (ii) The fascia covering the quadratus lumborum is also attached to this part of the rib. (iii) The internal intercostal muscle is inserted near the upper border, (iv) The costodiaphragmatic recess of the pleura is related to the medial three-fourths of the costal surface. (v) The diaphragm takes origin from the anterior end of this surface.

3. The following are attached to the outer surface:

   A. Attachments on the medial half
   (i) Costotransverse ligament (Fig. 13.8B).
   (ii) Lumbocostal ligament
   (iii) Lowest levator costae
   (iv) Iliocostalis and longissimus parts of sacrospinales.

   B. Attachments on the lateral half
   (i) Insertion of serratus posterior inferior
   (ii) Origin of latissimus dorsi
   (iii) Origin of external oblique muscle of abdomen

4. The intercostal muscles are attached to the upper border.

5. The structures attached to the lower border are:
   (i) Middle layer of thoracolumbar fascia.
   (ii) Lateral arcuate ligament, at the lateral border of the quadratus lumborum.
   (iii) Lumbocostal ligament near the head, extending to the transverse process of first lumbar vertebra.

**Ossification**

The eleventh and twelfth ribs ossify from one primary centre for the shaft and one secondary centre for the head.

**THE COSTAL CARTILAGES**

The costal cartilages represent the unossified anterior parts of the ribs. They are made up of hyaline cartilage. They contribute materially to the elasticity of the thoracic wall.

The medial ends of the costal cartilages of the first seven ribs are attached directly to the sternum. The eighth, ninth and tenth cartilages articulate with one another and form the costal margin. The cartilages of the eleventh and twelfth ribs are small. Their ends are free and lie in the muscles of the abdominal wall.

The direction of the costal cartilages is variable. As the first costal cartilage approaches the sternum it descends a little. The second cartilage is horizontal. The third ascends slightly. The remaining costal cartilages are angular. They continue the downward course of the rib for some distance, and then turn upwards to reach either the sternum or the next higher costal cartilage.

Each cartilage has two surfaces: anterior and posterior; two borders: superior and inferior and two ends: lateral and medial.

**Attachments on Costal Cartilages**

**Anterior Surface**

1. This surface of the first costal cartilage articulates with the clavicle and takes part in forming the sternoclavicular joint. It gives attachment to: (i) the sternoclavicular articular disc, (ii) the joint capsule, (iii) the sternoclavicular ligament, and (iv) the subclavius muscle.

2. The second to seventh costal cartilages give origin to the pectoralis major.

3. The remaining cartilages are covered by and give partial attachment to some of the flat muscles of the anterior abdominal wall. The internal oblique muscle is attached to the seventh, eighth and ninth
cartilages: and the rectus abdominis to the fifth, sixth and seventh cartilages.

**Posterior Surface**

1. The first cartilage gives origin to the sternothyroid muscle.
2. The second to sixth cartilages receive the insertion of the sternocostalis.
3. The seventh to twelfth cartilages give attachment to the transversus abdominis and to the diaphragm.

**Superior and Inferior Borders**

1. The borders give attachment to the internal intercostal muscles and the external intercostal membranes of the spaces concerned.
2. The fifth to ninth cartilages articulate with one another at the points of their maximum convexity, to form synovial joints.

**Lateral end**

The lateral end of each cartilage forms a primary cartilaginous joint with the rib concerned.

**Medial end**

1. The first cartilage forms a primary cartilaginous joint with the manubrium.
2. The second to seventh cartilages form synovial joints with the sternum.
3. The eighth, ninth and tenth cartilages are connected to the next higher cartilage.
4. The ends of the eleventh and twelfth cartilages are pointed and free.

---

**THE STERNUM**

The sternum is a flat bone, forming the anterior median part of the thoracic skeleton. In shape, it resembles a short sword. The upper part, corresponding to the handle is called the manubrium. The middle part, resembling the blade is called the body. The lowest tapering part forming the point of the sword is the xiphoid process or xiphisternum.

The sternum is about 17 cm long. It is longer in males than in females (Figs 13.9, 13.10).

**The Manubrium**

The manubrium is quadrilateral in shape. It is the thickest and strongest part of the sternum. It has two surfaces: anterior and posterior and four borders: superior, inferior, and two lateral.

The *anterior surface* is convex from side to side and concave from above downwards. The *posterior surface* is concave and forms the anterior boundary of the superior mediastinum. The *superior border* is thick, rounded and concave. It is marked by the suprasternal notch or jugular notch or interclavicular notch in the median part, and by the clavicular notch on each side. The clavicular notch articulates with the medial end of the clavicle to form the sternoclavicular joint.
The inferior border forms a secondary cartilaginous joint with the body of the sternum. The manubrium makes a slight angle with the body, convex forwards, called the sternal angle of Louis. The lateral border forms a primary cartilaginous joint with the first costal cartilage, and present a demi-facet for synovial articulation with the upper part of the second costal cartilage.

**Attachments on the Manubrium**

1. The anterior surface gives origin on either side to: (i) the pectoralis major, and (ii) the sternal head of the sternocleidomastoid (Fig. 13.11).
2. The posterior surface gives origin to: (i) the sternohyoid in upper part, and (ii) the sternothyroid in lower part. The lower half of this surface is related to the arch of the aorta. The upper half is related to the left brachiocephalic vein, the brachiocephalic artery, the left common carotid artery and the left subclavian artery. The lateral portions of the surface are related to the corresponding lung and pleura.
3. The suprasternal notch gives attachment to the lower fibres of the interclavicular ligament, and to the two subdivisions of the investing layer of cervical fascia.
4. The margins of each clavicular notch give attachment to the capsule of the corresponding sternoclavicular joint.

The Body of the Sternum

The body is longer, narrower and thinner than the manubrium. It is widest close to its lower end opposite the articulation with the fifth costal cartilage. It has two surfaces: anterior and posterior; two lateral borders and two ends: upper and lower.

1. The anterior surface is nearly flat and directed forwards and slightly upwards. It is marked by three ill-defined transverse ridges, indicating the lines of fusion of the four small segments called sternebrae.
2. The posterior surface is slightly concave and is marked by less distinct transverse lines.
3. The lateral borders form synovial joints with the lower part of the second costal cartilage, the third to sixth costal cartilages, and the upper half of the seventh costal cartilage (Fig. 13.11).
4. The upper end forms a secondary cartilaginous joint with the manubrium, at the sternal angle.
5. The lower end is narrow and forms a primary cartilaginous joint with the xiphisternum.

**Attachments on the Body of the Sternum**

1. The anterior surface gives origin on either side to the pectoralis major muscle.
2. The lower part of the posterior surface gives origin on either side to the sternocostalis muscle.
3. On the right side of the median plane, the posterior surface is related to the anterior border of the right lung and pleura. On the left side the upper two pieces of the body are related to the left lung and pleura, and the lower two pieces to the pericardium (Fig. 13.12).
4. Between the facets for articulation with the costal cartilages, the lateral borders provide attachment to the external intercostal membranes and to the internal intercostal muscles.
The Xiphoid Process

The xiphoid process is the smallest part of the sternum. It is at first cartilaginous, but in the adult it becomes ossified near its upper end. It varies greatly in shape and may be bifid or perforated. It lies in the floor of the epigastric fossa.

Attachments on the Xiphoid Process

1. The anterior surface provides insertion to the medial fibres of the rectus abdominis, and to the aponeuroses of the external and internal oblique muscles of the abdomen.
2. The posterior surface gives origin to the diaphragm. It is related to the anterior surface of the liver.
3. The lateral borders of the xiphoid process give attachment to the aponeuroses of the internal oblique and transversus abdominis muscles.
4. The upper end forms a primary cartilaginous joint with the body of the sternum.
5. The lower end affords attachment to the linea alba.

Development and Ossification

The sternum develops by fusion of two sternal plates formed on either side of the midline. The fusion of the two plates takes place in a craniocaudal direction. Nonfusion of the plates causes ectopia cordis, where the heart lies uncovered on the surface. Partial fusion of the plates may lead to the formation of sternal foramina, bifid xiphoid process, etc.

In the cartilaginous sternum, five double bony centres appear from above downwards during the fifth, sixth, seventh, eighth and ninth fetal months. The upper centre forms the manubrium. The other centres form four sternebrae, which fuse with each other from below upwards during puberty. Fusion is complete by 25 years of age. The manubriosternal joint which is a secondary cartilaginous usually persists throughout life. In only about 10% of subjects, fusion may occur in old age.

The centre for the xiphoid process appears during the third year or later. It fuses with the body at about 40 years.

The vertebral column is made up of 33 vertebrae: seven cervical, twelve thoracic, five lumbar, five sacral and four coccygeal. In the thoracic, lumbar I and sacral regions, the number of vertebrae corresponds to the number of spinal nerves, each nerve I lying below the corresponding vertebra. In the cervical I region, there are eight nerves, the upper seven lying I above the corresponding vertebrae and the eighth below the seventh vertebra. In the coccygeal region, there is only one coccygeal nerve.

Sometimes the vertebrae are also grouped accord- ing to their mobility. The movable or true vertebrae I include the seven cervical, twelve thoracic and five lumbar vertebrae, making a total of 24. Twelve thoracic vertebrae have ribs attached to them. The fixed or false vertebrae include those of the sacrum and coccyx.

The length of the spine is about 70 cm in males and about 60 cm in females. The intervertebral discs contribute one-fifth of the length of the vertebral column.

As a result of variations in the width of the vertebrae, the vertebral column can be said to be made up of four pyramids (Fig. 13.13). This arrangement has a functional bearing. The narrowing of the vertebral column at the level of the disc between fourth thoracic and fifth thoracic vertebrae is partly compensated for by the transmission of weight to the lower thoracic region through the sternum and ribs.

Curvatures of the Vertebral Column

In Sagittal Plane

1. Primary curves are present at birth and due to the shape of the vertebral bodies. The primary curves are thoracic and sacral, both of which are concave forwards.
2. Secondary curves are postural and are mainly due to the shape of the intervertebral disc. The
secondary or compensatory curves are cervical and lumbar, both of which are convex forwards. The cervical curve appears during four to five months after birth when the infant starts supporting its head; the lumbar curve appears during twelve to eighteen months when the child assumes the upright posture.

In Coronal Plane (lateral curve)

There is slight lateral curve in the thoracic region with its concavity towards the left. It is possible due to the greater use of the right upper limb and the pressure of the aorta.

The curvatures add to the elasticity of the spine, and the number of curves gives it a higher resistance to weight than would be afforded by a single curve.

Parts of a Typical Vertebra

A typical vertebra is made up of the following parts. 1. The body lies anteriorly. It is shaped like a short cylinder, being rounded from side to side and having flat upper and lower surfaces that are attached to those of adjoining vertebrae by intervertebral discs (Fig. 13.14).

1. The pedicles: right and left are short rounded bars that project backwards, and somewhat laterally, from the posterior aspect of the body.
2. Each pedicle is continuous, posteromedially, with a vertical plate of bone called the lamina. The laminae of the two sides pass backwards and medially to meet in the midline. The pedicles and laminae together constitute the vertebral or neural arch.
3. Bounded anteriorly by the posterior aspect of the body, on the sides by the pedicles, and behind by the lamina, there is a large vertebral foramen.

Each vertebral foramen forms a short segment of the vertebral canal that runs through the whole length of the vertebral column and lodges the spinal cord.

1. Passing backwards and usually downwards from the junction of the two laminae there is the spine or spinous process (Fig. 13.15).
2. Passing laterally and usually somewhat downwards from the junction of each pedicle and the corresponding lamina, there is a transverse process.
The spinous and transverse processes serve as levers for muscles acting on the vertebral column.

From a morphological point of view the transverse processes are made up of two elements, the transverse element and the costal element. In the thoracic region, the two elements remain separate, and the costal elements form the ribs. In the rest of the vertebral column, the derivatives of costal element are different from those derived from transverse element. This is shown in Table 13.1.

7. Projecting upwards from the junction of the pedicle and the lamina there is on either side, a superior articular process; and projecting downwards there is an inferior articular process (Fig. 13.16). Each process bears a smooth articular facet: the superior facet is directed posteriorly and somewhat laterally, and the inferior facet is directed forwards and somewhat medially. The superior facet of one vertebra articulates with the inferior facet of the vertebra above it. Two adjoining vertebrae, therefore, articu-

Typical Thoracic Vertebra

A. The body is heart-shaped with roughly the same measurements from side to side and anteroposteriorly. On each side it bears two costal demifacets. The superior costal demifacet is larger and placed on the upper border of the body near the pedicle. It articulates with the head of the numerically corresponding rib. The inferior costal demifacet is smaller and placed on the lower border in front of the inferior vertebral notch. It articulates with the next lower rib.

B. The vertebral foramen is comparatively small and circular.

C. The vertebral arch
1. The pedicles are directed straight backwards. The superior vertebral notch is shallow, while the inferior vertebral notch is deep and conspicuous.
2. The laminae overlap each other from above.
3. The superzorarticular processes project upwards from the junction of the pedicles and laminae. The articular facets are flat and are directed backwards and a little laterally and upwards. This direction permits rotatory movements of the spine.
4. The inferior articular processes are fused to the laminae. Their articular facets are directed forwards and slightly downwards and medially.
5. The transverse processes are large, and are directed laterally and backwards from the junction of the pedicles and laminae. The anterior surface of each process bears a facet near its tip, for articulation with the tubercle of the corresponding rib. In the upper six vertebrae, the costal facets on the transverse processes are concave, and face forwards and laterally. In lower six, the facets are flat and face upwards, laterally and slightly forwards (see costotransverse joints below).
6. The spine is long, and is directed downwards and backwards. The fifth to ninth spines are the longest, more vertical and overlap each other. The upper and lower spines are less oblique in direction.

**Attachments on a Typical Thoracic Vertebra**

1. The upper and lower borders of the body give attachment, in front and behind respectively to the anterior and posterior longitudinal ligaments.
2. The upper borders and lower parts of the anterior surfaces of the laminae provide attachment to the ligamenta flava.
3. The transverse process gives attachment to: (i) the lateral costotransverse ligament at the tip, (ii) the superior costotransverse ligament along the lower border; (iii) the inferior costotransverse ligament along the anterior surface; (iv) the intertransverse muscles to upper and lower borders; and (v) the levator costae on the posterior surface.
4. The spines give attachment to the supraspinous and interspinous ligaments. They also give attachment to several muscles including the trapezius, the rhomboideus, the latissimus dorsi, the serrati posterior, superior and inferior, and many deep muscles of the back.

**Ossification of a Thoracic Vertebra**

The ossification is similar to that of a typical vertebra. It ossifies in cartilage from three primary and five secondary centres.

The three primary centres, one for the centrum and one for each half of the neural arch, appear during eighth to ninth week of fetal life. At birth the vertebra consists of three parts, the centrum and two halves of the neural arch. The two halves of the neural arch fuse posteriorly during the first year of life. The neural arch is joined with the centrum by the neurocentral synchondrosis. Bony fusion occurs here during the third to sixth years of life.

Five secondary centres: one for the upper surface and one for the lower surface of the body, one for each transverse process, and one for the spine appear at about the 15th year and fuse with the rest of the vertebra at about the 25th year.

Failure of fusion of the two halves of the neural arch results in 'spina bifida'. Sometimes the body ossifies from two primary centres, and if one centre fails to develop, one half, right or left of the body is missing. This results in a hemivertebra and lateral bend in the vertebral column or scoliosis.

**Jalie First Thoracic Vertebra**

1. The body of this vertebra resembles that of a cervical vertebra. It is broad and not heart-shaped.

Its upper surface is lipped laterally and bevelled anteriorly.

The superior costal facet on the body is complete (Fig. 13.17). It articulates with the head of the first rib. The inferior costal facet is a 'demifacet' for the second rib.

1. The spine is thick, long and nearly horizontal.
2. The superior vertebral notches are well marked, as in cervical vertebrae.

**The Ninth Thoracic Vertebra**

The ninth thoracic vertebra resembles a typical thoracic vertebra except that the body has only the superior costal demifacets. The inferior costal facets are absent (Fig. 13.17).

**The Tenth Thoracic Vertebra**

The tenth thoracic vertebra resembles a typical thoracic vertebra except that the body has a single complete superior costal facet on each side, extending on to the root of the pedicle (Fig. 13.17).
The Eleventh Thoracic Vertebrae

1. The body has a single large costal facet on each side, extending on to the upper part of the pedicle (Fig. 13.17).
2. The transverse process is small, and has no articular facet.

Sometimes it is difficult to differentiate between thoracic tenth and eleventh vertebrae.

The Twelfth Thoracic Vertebra

1. The shape of the body, pedicles, transverse processes and spine are similar to those of a lumbar vertebra. However, the body bears a single costal facet on each side, which lies more on the lower part of the pedicle than on the body.
2. The transverse process is small and has no facet, but has superior, inferior and lateral tubercles (Fig. 13.17).
3. The inferior articular facets are lumbar in type. These are everted and are directed laterally, but the superior articular facets are thoracic in type.

JOINTS OF THE THORAX

Manubriosternal Joint

Manubriosternal joint is a secondary cartilaginous joint. It permits slight movements of the body of the sternum on the manubrium during respiration. In about 10% of subjects, the joint may be obliterated by fusion of the two bones.

Costovertebral Joints

The head of a typical rib articulates with its own vertebra, and also with the body of the next higher vertebra, to form two plane synovial joints separated by an intra-articular ligament. This ligament is attached to the ridge on the head of the rib and to the intervertebral disc. Other ligaments of the joint include a capsular ligament and a triradiate ligament. The middle band of the triradiate ligament forms the hypochondral bow (Fig. 13.5), uniting the joints of the two sides.

Costotransverse Joints

The tubercle of a typical rib articulates with the transverse process of the corresponding vertebra to form a synovial joint. The capsular ligament is strengthened by three costotransverse ligaments. The superior costotransverse ligament has two laminae which extend from the crest on the neck of the rib to the transverse process of the vertebra above. The inferior costotransverse ligament passes from the posterior surface of the neck to the transversa process of its own vertebra. The lateral costotransverse ligament connects the lateral non-articular part of the tubercle to the tip of the transverse process. The articular facets on the tubercles of the upper six ribs are convex, and permit rotation of the rib neck for pump-handle movements of these ribs (Fig. 13.18). Rotation of rib-neck backwards causes elevation of second to sixth ribs with moving forwards and upwards of the sternum. This increases the anteroposterior diameter of the thorax (Fig. 13.19).

Fig. 13.18: A section through the costotransverse joints from the third to the ninth inclusive. Contrast the concave facets on the third to the ninth inclusive. Contrast the concave facets on the upper four with the flattened facets on the lower three transverse processes.

The articular surfaces of the seventh to tenth ribs are flat, permitting up and down gliding movements or bucket-handle movements of the lower ribs. When the neck of seventh to tenth ribs moves upwards, backwards and medially the result is increase in infrasternal angle. This causes increase in transverse diameter of thorax (Fig. 13.20).

For explanation of the terms 'pump-handle' and 'bucket handle' movements see 'Respiratory Movements'.

Costochondral Joints

Each rib is continuous anteriorly with its cartilage, to form a primary cartilaginous joint. No movements are permitted at these joints.
Chondrosternal Joints

The first chondrosternal joint is a primary cartilaginous joint, it does not permit any movement. This helps in the stability of the shoulder girdle and of the upper limb.

The second to seventh costal cartilages articulate with the sternum by synovial joints. Each joint has a single cavity except in the second joint where the cavity is divided in two parts. The joints are held together by the capsular and radiate ligaments.

Interchondral Joints

The fifth to ninth costal cartilages articulate with one another by synovial joints. The tenth cartilage is united to the ninth by fibrous tissue.

The movements taking place at the various joints described above are considered under 'Respiratory Movements'.

Intervertebral Joints

Adjoining vertebrae are connected to each other at three joints. There is a median joint between the vertebral bodies, and two joints—right and left—between the articular processes.

The joints between the articular processes are plane synovial joints.

The joint between the vertebral bodies is a symphysis (secondary cartilaginous joint). The surfaces of the vertebral bodies are lined by thin layers of hyaline cartilage. Between these layers of hyaline cartilage there is a thick plate of fibrocartilage which is called the intervertebral disc.

Intervertebral Discs

These are fibrocartilaginous discs which intervene between the bodies of adjacent vertebrae, and bind them together. Their shape corresponds to that of the vertebral bodies between which they are placed. The thickness of the disc varies in different regions of the vertebral column, and in different parts of the same disc. In the cervical and lumbar regions, the discs are thicker in front than behind, while in the thoracic region they are of uniform thickness. The discs are thinnest in the upper thoracic region, and thickest in the lumbar region.

The discs contribute about one-fifth of the length of the vertebral column. The contribution is greater in the cervical and lumbar regions than in the thoracic region.

Each disc is made up of the following two parts:

1. The **nucleus pulposus** is the central part of the disc. It is soft and gelatinous at birth. It is kept under tension and acts as a hydraulic shock absorber. With advancing age the elasticity of the disc is much reduced (Fig. 13.21).

2. The **annulus fibrosus** forms the peripheral part of the disc. It is made up of a narrower outer zone of collagenous fibres and a wider inner zone of fibrocartilage. The fibres form laminae that are arranged in the form of incomplete rings. The rings are connected by strong fibrous bands. The outer collagenous fibres blend with the anterior and posterior longitudinal ligaments.
Functions

1. The intervertebral discs give shape to the vertebral column.
2. They act as a remarkable series of shock absorbers or buffers.
3. Because of their elasticity they allow slight movement of vertebral bodies on each other, more so in the cervical and lumbar regions. When the slight movements at individual discs are added together they become considerable.

Ligaments Connecting Adjacent Vertebrae

Apart from the intervertebral discs and the capsules around the joints between the articular processes, adjacent vertebrae are connected by several ligaments which are as follows:

1. The anterior longitudinal ligament passes from the anterior surface of the body of one vertebra to another. Its upper end reaches the basilar part of the occipital bone (Fig. 13.21).
2. The posterior longitudinal ligaments present on the posterior surface of the vertebral bodies within the vertebral canal. Its upper end reaches the body of the axis vertebra beyond which it is continuous with the membrana tectoria.
3. The intertransverse ligaments connect adjacent transverse processes.
4. The interspinous ligaments connect adjacent spines.
5. The supraspinous ligaments connect the tips of the spines of vertebrae from the seventh cervical to the sacrum. In the cervical region, they are replaced by the ligamentum nuchae.
6. The ligamenta flava (singular = ligamentum flavum) connect the laminae of adjacent vertebrae. They are made up mainly of elastic tissue.

Movements of the Vertebral Column

Movements between adjacent vertebrae occur simultaneously at all the three joints connecting them. Movement between any two vertebrae is slight. However, when the movements between several vertebrae are added together the total range of movement becomes considerable. The movements are those of flexion, extension, lateral flexion and a certain amount of rotation. The range of movement differs in different parts of the vertebral column. This is influenced by the thickness and flexibility of the intervertebral discs and by the orientation of the articular facets. Flexion and extension occur freely in the cervical and lumbar region, but not in the thoracic region. Rotation is free in the thoracic region, and restricted in the lumbar and cervical regions.

RESPIRATORY MOVEMENTS

Introduction

The lungs expand passively during inspiration and retract during expiration. These movements are governed by the following two factors.

(i) Alterations in the capacity of the thorax are brought about by movements of the thoracic wall. Increase in volume of the thoracic cavity creates a negative intrathoracic pressure which sucks air into the lungs. Movements of
the thoracic wall occur chiefly at the costovertebral and manubriosternal joints, (ii) Elastic recoil of the pulmonary alveoli and of the thoracic wall expels air from the lungs during expiration.

**Principles of Movements**

1. Each rib may be regarded as a lever, the fulcrum of which lies just lateral to the tubercle. Because of the disproportion in the length of the two arms of the lever, the slight movements at the vertebral end of the rib are greatly magnified at the anterior end (Fig. 13.22).

2. The anterior end of the rib is lower than the posterior end. Therefore, during elevation of the rib, the anterior end also moves forwards. This occurs mostly in the vertebrosternal ribs. In this way, the anteroposterior diameter of the thorax is increased. Along with the up and down movements of the second to sixth ribs, the body of the sternum also moves up and down called 'pump-handle movements'.

3. The middle of the shaft of the rib lies at a lower level than the plane passing through the two ends. Therefore, during elevation of the rib, the shaft also moves outwards. This causes increase in the transverse diameter of the thorax.

4. The thorax resembles a cone, tapering upwards. As a result each rib is longer than the next higher rib. On elevation the larger lower rib comes to occupy the position of the smaller upper rib. This also increases the transverse diameter of the thorax (Fig. 13.24).

**Summary of the Factors Producing Increase in Diameters of the Thorax**

The anteroposterior diameter is increased:

(i) Mainly by the 'pump-handle' movements of the sternum brought about by elevation of the vertebrosternal second to sixth ribs.

(ii) Partly by elevation of the seventh to tenth vertebrochondral ribs. The transverse diameter is increased:

   (i) Mainly by the 'bucket-handle' movements of the seventh to tenth vertebrochondral ribs, (ii) Partly by elevation of the second to sixth vertebrosternal ribs. The vertical diameter is increased by descent of the diaphragm as it contracts.

**Respiratory Muscles**

1. During quiet breathing, inspiration is brought about chiefly by the diaphragm and partly by the intercostal muscles: quiet expiration occurs passively by the elastic recoil of the pulmonary alveoli and thoracic wall.

2. During forced breathing, inspiration is brought about by the diaphragm, the intercostal muscles,
the sternocleidomastoids, the scaleni, the serratus anterior, the pectoralis minor, and the erector spinae. The alaequae nasi open up the external nares.

Forced expiration is brought about by the muscles of the abdominal wall and by the latissimus dorsi.

**Respiratory Movements during Different Types of Breathing**

**Inspiration**

1. *Quiet Inspiration*
   
   (i) The anteroposterior diameter of the thorax is increased by elevation of the second to sixth ribs. The first rib remains fixed.
   
   (ii) The transverse diameter is increased by elevation of the seventh to tenth ribs.
   
   (iii) The vertical diameter is increased by descent of the diaphragm.

2. *Deep Inspiration*
   
   (i) Movements during quiet inspiration are increased, (ii) The first rib is elevated directly by the scaleni, and indirectly by the sternocleidomastoids, (iii) The concavity of the thoracic spine is reduced by the erector spinae.

3. *Forced Inspiration*
   
   (i) All the movements described are exaggerated. (ii) The scapulae are elevated and fixed by the trapezius, the levator scapulae and the rhomboideus, so that the serratus anterior and the pectoralis minor muscles may act on the ribs. (iii) The action of the erector spinae is appreciably increased.

**Expiration**

1. *Quiet Expiration*

   The air is expelled mainly by the elastic recoil of the chest wall and pulmonary alveoli, and partly by the tone of the abdominal muscles.

2. *Deep and Forced Expiration*

   Deep and forced expiration is brought about by strong contraction of the abdominal muscles and of the latissimus dorsi.

**CLINICAL ANATOMY**

In dyspnoea or difficult breathing, the patients are most comfortable on sitting up, leaning forwards and fixing the arms. In the sitting posture, the position of diaphragm is lowest allowing maximum ventilation. Fixation of the arms fixes the scapulae, so that the serratus anterior and pectoralis minor may act on the ribs to good advantage.

The height of the diaphragm in the thorax is variable according to the position of the body and tone of the abdominal muscles. It is highest on lying supine, so the patient is extremely uncomfortable, as he/she needs to exert immensely for inspiration. The diaphragm is lowest while sitting. The patient is quite comfortable as the effort required for inspiration is the least.

The diaphragm is midway in position while standing, but the patient is too ill or exhausted to stand. So dyspnoeic patients feel comfortable while sitting.
The thorax is covered by muscles of pectoral region of upper limb. In addition, the intercostal muscles and membranes fill up the gaps between adjacent ribs and cartilages. These muscles provide integrity to the thoracic wall. A right and left pair of thoracic nerves fulfil the exact definition of the dermatome.

The posterior intercostal vein, posterior intercostal artery and intercostal nerve (VAN) lie from above downwards in the costal groove of the ribs.

Sympathetic part of autonomic nervous system starts from the lateral horns of thoracic 1 to thoracic 12 segments of the spinal cord. It continues up to lumbar 2 segment.

**Coverings of the Thoracic Wall**

The thoracic wall is covered from outside to inside by the following structures: skin, superficial fascia, deep fascia, and extrinsic muscles. The extrinsic muscles covering the thorax are as follows.

**A. Muscles of the Upper Limb**

i. Pectoralis major
ii. Trapezius
iii. Serratus anterior
iv. Pectoralis minor
v. Latissimus dorsi
vi. Levator scapulae
vii. Rhomboideus major
viii. Rhomboideus minor
ix. Serratus posterior superior
x. Serratus posterior inferior
B. Muscles of the Abdomen
   (i) Rectus abdominis,  (ii) External oblique.
C. Muscles of the Back
Erector spinae (sacrospinalis).
In addition to the muscles listed above, a number of other muscles of the abdomen and of the head and neck are attached to
the margins of the two apertures of the thorax.

THORACIC WALL PROPER

The thoracic cage forms the skeletal framework of the wall of the thorax. The gaps between the ribs are called intercostal
spaces. They are filled by the intercostal muscles and contain the intercostal nerves, vessels and lymphatics.

Intercostal Muscles
These are: (i) the external intercostal muscle, (ii) the internal intercostal muscle, and (iii) the transversus thoracis muscle which
is divisible into three parts, namely the subcostalis, the intercostalis intimi and the sternocostalis. The attachments of these
muscles are given in Table 14.1.

Extent
The external intercostal muscle extends from the tubercle of the rib posteriorly to the costochondral junction anteriorly.
Between the costochondral junction and the sternum it is replaced by the external or anterior intercostal membrane. The
posterior end of the muscle is continuous with the posterior fibres of the superior costotransverse ligament (Fig. 14.1).
The internal intercostal muscle extends from the lateral border of the sternum to the angle of the rib. Beyond the angle it
becomes continuous with the internal or posterior intercostal membrane, which is continuous with the anterior fibres of the
superior costotransverse ligament.

Fig. 14.1: Two layers of a typical intercostal space.

The subcostalis is confined to the posterior part of the lower intercostal spaces only.

The intercostalis intimi is confined to the middle two-fourths of the intercostal spaces (Fig. 14.2). The sternocostalis is present in relation to the anterior parts of the upper intercostal spaces.

Detach the serratus anterior and the pectoralis major muscles from the upper ribs. Note the external intercostal muscle in the second and third intercostal spaces. Its fibres run antero-inferiorly. Follow it forwards to the external intercostal membrane which replaces it between the costal cartilages.

Cut the external intercostal membrane and muscle along the lower border of two spaces. Reflect them upwards to expose the internal intercostal muscle. The direction of its fibres is postero-inferiorly.

Follow the lateral cutaneous branch of one intercostal nerve to its trunk deep to internal intercostal muscle. Trace the nerve and accompanying vessels round the thoracic wall. Note their collateral branches lying along the upper margin of the rib below. Trace the muscular branches of the trunk of intercostal nerve and its collateral branch. Trace the anterior cutaneous nerve as well.

Identify the deepest muscle in the intercostal space, the innermost intercostal muscle. This muscle is deficient in the anterior and posterior ends of the intercostal spaces, where the neurovascular bundle rests directly on the parietal pleura.

Expose the internal thoracic artery 1 cm from the lateral margin of sternum by carefully removing the intercostal muscles and membranes from the upper three intercostal spaces. Trace the artery through the upper six intercostal spaces and identify its two terminal branches. Trace its vena comitantes upwards till third costal cartilage where
these join to form internal thoracic vein, which drains into the brachiocephalic vein.

Follow the course and branches of both anterior and posterior intercostal arteries including the course and tributaries of azygos vein.

**Direction of Fibres**

1. The fibres of the external intercostal muscle run downwards, forwards and medially.
2. The fibres of the internal intercostal run downwards, backwards and laterally, i.e., at right angles to those of the external intercostal.
3. The fibres of the transversus thoracis run in the same direction as those of the internal intercostal.

**Nerve Supply**

The intercostal muscles are supplied by the intercostal nerves of the spaces in which they lie.

**Actions of the Intercostal Muscles**

1. The main action of the intercostal muscles is to prevent retraction of the intercostal spaces during expiration, and, their bulging outwards during inspiration.

1. The external intercostals, interchondral portions of the internal intercostals, and the levator costae may elevate the ribs during inspiration.
2. The internal intercostals except for the interchondral portions and the transversus thoracis may depress the ribs or cartilages during expiration.

**Nerves and Vessels of the Thoracic Wall**

**Intercostal Nerves**

The intercostal nerves are the anterior primary rami of thoracic one to thoracic eleven (Fig. 14.3) spinal nerves after the dorsal primary ramus has been given off. The anterior primary ramus of the twelfth thoracic nerve forms the subcostal nerve. In addition to supplying the intercostal spaces, the upper two intercostal nerves also supply the upper limb; and the lower five intercostal nerves; seventh to eleventh thoracic also supply abdominal wall. The latter are, therefore, said to be thoracoabdominal nerves. The remaining nerves; third to sixth thoracic supply only the thoracic wall; they are called *typical intercostal nerves*.

The subcostal nerve is distributed to the abdominal wall and to the skin of the buttock.

**Course and Relations of a Typical Intercostal Nerve**

1. Each nerve passes below the neck of the rib of the same number and enters the costal groove.
2. In the costal groove the nerve lies below the posterior intercostal vessels. The relationship of structures in the costal groove from above downwards is vein-artery-nerve (VAN) (Fig. 14.2).

In the posterior part of the costal groove, the nerve lies between the pleura, with the endothoracic fascia and the internal intercostal membrane.

In the greater part of the space, the nerve lies between the intercostalis intimi and the internal intercostal muscle (Fig. 14.4).

3. Near the sternum the nerve crosses in front of the internal thoracic vessels and the sternocostalis muscle. It then pierces the internal intercostal muscle, the external intercostal membrane and the pectoralis major muscle to terminate as the anterior cutaneous nerve of the thorax.

Branches and Distribution

Muscular Branches

1. Numerous muscular branches supply the intercostal muscles, the transversus thoracis and the serratus posterior superior.

2. A collateral branch arises near the angle of the rib and runs in the lower part of the space in the same neurovascular plane. It supplies muscles of the space. It also supplies the parietal pleura, parietal peritoneum in case of lower nerves and the periosteum of the rib.

Cutaneous Branches

1. The lateral cutaneous branch arises near the angle of the rib and accompanies the main trunk up
to the lateral thoracic wall where it pierces the intercostal muscles and other muscles of the body wall along the midaxillary line. It is distributed to the skin after dividing into anterior and posterior branches.

2. The anterior cutaneous branch emerges on the side of the sternum to supply the overlying skin after dividing into medial and lateral branches.

**Communicating Branches**

1. Each nerve is connected to a thoracic sympathetic ganglion by a distally placed white and a proximally placed grey ramus communicans.
2. The lateral cutaneous branch of the second intercostal nerve is known as the intercostobrachial nerve. It supplies the skin of the floor of the axilla and of the upper part of the medial side of the arm.

**CLINICAL ANATOMY**

1. Irritation of the intercostal nerves causes severe pain which is referred to the front of the chest or abdomen, i.e. at the peripheral termination of the nerve. This is known as root pain or girdle pain.
2. Pus from the vertebral column tends to track around the thorax along the course of the neurovascular bundle, and may point at any of the three sites of exit of the branches of a thoracic nerve; one dorsal primary ramus and two cutaneous branches.

---

![Diagram of intercostal nerves](image)

**Fig. 14.4:** Scheme showing the course and branches of a typical intercostal nerve.

---

**Bercostal Arteries**

Each intercostal space contains one posterior intercostal artery with its collateral branch and two interior intercostal arteries. The greater part of the face is supplied by the posterior intercostal artery (Fig. 14.5).

**Interior Intercostal Arteries**

These are eleven in number on each side, one in each space.

1. The first and second posterior intercostal arteries arise from the superior intercostal artery, which is a branch of the costocervical trunk.
2. The third to eleventh arteries arise from the descending thoracic aorta (Fig. 14.6).

**Course and Relations**

*In front of the vertebrae*: The right posterior intercostal arteries are longer than the left, and pass behind the oesophagus, the thoracic duct, the azygos vein and the sympathetic chain (Fig. 14.7).
The left posterior intercostal arteries pass behind the hemiazygos vein and the sympathetic chain (Fig. 14.5).

In the intercostal space: The artery is accompanied by the intercostal vein and nerve, the relationship from above downwards being vein-artery-nerve (VAN).

The neurovascular bundle runs forwards in the costal groove, first between the pleura and the
internal intercostal membrane and then between the internal intercostal and intercostalis intimi muscles.

**Termination**

Each posterior intercostal artery ends at the level of the costochondral junction by anastomosing with the upper anterior intercostal artery of the space (Fig. 14.5).

**Branches**

1. A dorsal branch supplies the muscles and skin of the back, and gives off a spinal branch to the spinal cord and vertebrae (Fig. 14.5).
2. A collateral branch arises near the angle of the rib, descends to the upper border of the lower rib, and ends by anastomosing with the lower anterior intercostal artery of the space.
3. Muscular arteries are given off to the intercostal muscles, the pectoral muscles and the serratus anterior.
4. A lateral cutaneous branch accompanies the nerve of the same name.
5. Mammary branches arise from the second, third and fourth arteries and supply the mammary gland.
6. The right bronchial artery arises from the right third posterior intercostal artery.

**Anterior Intercostal Arteries**

There are nine intercostal spaces anteriorly. There are two anterior intercostal arteries in each space. In
upper anterior intercostal arteries end at the costo-chondral junction by anastomosing with the posterior intercostal arteries. The lower arteries end by anastomosing with the collateral branches of the posterior intercostal arteries.

**Intercostal Veins**

There are two *anterior intercostal veins* in each of the upper nine spaces. They accompany the corresponding arteries. In the upper six spaces, the veins end in the internal thoracic vein. In the succeeding spaces, they end in the musculophrenic vein.

There is one *posterior intercostal vein* and one collateral vein in each intercostal space. Each vein accompanies the corresponding artery and lies superior to the artery. The tributaries of these veins correspond to the branches of the arteries. They include veins from the vertebral canal, the vertebral venous plexus, and the muscles and skin of the back.
vein accompanying the collateral branch of the artery drains into the posterior intercostal vein.

The mode of termination of the posterior intercostal veins is different on the right and left sides as given in Table 14.2, and shown in Fig. 14.8.

The azygos and hemiazygos veins are described after.

Lymphatics of an Intercostal Space

Lymphatics from the anterior part of the spaces pass to the anterior intercostal or internal mammary lodes which lie along the internal thoracic artery. Their efferents unite with those of the tracheobronchial and brachiocephalic nodes to form the bronchomediastinal trunk, which joins the subclavian trunk on the right side and the thoracic duct on the left side.

Lymphatics from the posterior part of the space pass to the posterior intercostal nodes which lie on the heads and necks of the ribs. Their efferents in the lower four spaces unite to form a trunk which descends and opens into the cisterna chyli. The efferents from the upper spaces drain into the thoracic duct on the left side and into the right lymphatic duct on the right side.

INTERNAL THORACIC ARTERY

Origin

Internal thoracic artery arises from the inferior aspect of the first part of the subclavian artery opposite the thyrocervical trunk. The origin lies 2 cm above the sternal end of the clavicle (Fig. 14.9).

Surface Marking

Internal thoracic artery is marked by joining the following points.

1. A point 1 cm above the sternal end of the clavicle, 3.5 cm from the median plane (Fig. 14.10).
2. Points marked over the upper 6 costal cartilages at a distance of 1.25 cm half from the lateral sternal border.
internal intercostal muscles, and (vi) the first six intercostal nerves.

Posteriorly: (i) The endothoracic fascia and pleura up to the second or third costal cartilage. Below this level the sternocostalis muscle separates the artery from the pleura (Fig. 14.11).

The artery terminates in the sixth intercostal space by dividing into the superior epigastric and musculophrenic arteries.

The artery is accompanied by two venae comitantes which unite at the level of the third costal cartilage to form the internal thoracic or internal mammary vein. The vein runs upwards along the medial side of the artery to end in the brachiocephalic vein at the inlet of the thorax.

A chain of lymph nodes lies along the artery.

3. The last point is marked in the sixth space 1.25 cm half from the lateral sternal border.

Course and Relations

Above the first costal cartilage it runs downwards, forwards and medially, behind: (i) The sternal end of the clavicle, (ii) the internal jugular vein, (iii) the brachiocephalic vein, (iv) the first costal cartilage, and (v) the phrenic nerve. It descends in front of the cervical pleura.

Below the first costal cartilage the artery runs vertically downwards up to its termination in the 6th intercostal space. Its relations are as follows:

Anteriorly: (i) Pectoralis major, (ii) upper six costal cartilages, (iii) external intercostal membranes, (iv)
Branches

1. The pericardiophrenic artery arises in the root of the neck and accompanies the phrenic nerve to reach the diaphragm. It supplies the pericardium and the pleura.

2. The mediastinal arteries are small irregular branches that supply the thymus, in front of the pericardium, and the fat in the mediastinum.

3. Two anterior intercostal arteries are given to each of the upper six intercostal spaces.

4. The perforating branches accompany the anterior cutaneous nerves. In the female, the perforating branches in the second, third and fourth spaces are large and supply the breast.

5. The superior epigastric artery runs downwards behind the seventh costal cartilage and enters the rectus sheath by passing between the sternal and costal slips of the diaphragm. Its further course is described in Vol. 2 of this book.

6. The musculophrenic artery runs downwards and laterally behind the seventh, eighth, and ninth
costal cartilages. It gives two anterior intercostal branches to each of these three spaces. It perforates the diaphragm near the 9th costal cartilage and terminates by anastomosing with other arteries on the undersurface of the diaphragm.

Note that through its various branches the internal thoracic artery supplies the anterior thoracic and abdominal walls from the clavicle to the umbilicus.

THE AZYGOS VEIN

The azygos vein drains the thoracic wall and the upper lumbar region (Figs 14.8, 20.6B, C). It forms an important channel connecting the superior and inferior vena cavae. The term 'azygos' means unpaired. The vein occupies the upper part of the posterior abdominal wall and the posterior mediastinum.

Formation

The azygos vein is formed by union of the lumbar azygos, right subcostal and right ascending lumbar veins.

1. The lumbar azygos vein may be regarded as the abdominal part of the azygos vein. It lies to the right of the lumbar vertebrae. Its lower end communicates with the inferior vena cava.
2. The right subcostal vein accompanies the corresponding artery.
3. The ascending lumbar vein is formed by vertical anastomoses that connect the lumbar veins. Usually, the right subcostal and ascending lumbar veins join to form a common channel that joins the lumbar azygos vein. Occasionally the lumbar azygos vein is absent. The azygos vein is then formed by union of the right subcostal and ascending lumbar veins.

Course

1. The azygos vein enters the thorax by passing through the aortic opening of the diaphragm.
2. The azygos vein then ascends up to fourth thoracic vertebra where it arches forwards over the root of the right lung and ends by joining the posterior aspect of the superior vena cava just before the latter pierces the pericardium (Fig. 15.1).

Relations

Anteriorly: Oesophagus.
Posteriorly: (i) Lower eight thoracic vertebrae, and (ii) right posterior intercostal arteries.
To the left: (i) Thoracic duct and aorta in lower part, and (ii) oesophagus, trachea and vagus in the upper part.

Tributaries

1. Right superior intercostal vein formed by union of the second, third and fourth posterior intercostal veins.
2. Fifth to eleventh right posterior intercostal veins (Fig. 14.8).
3. Hemiazygos vein at the level of eight thoracic vertebra T8.
4. Accessory hemiazygos vein at the level of eight thoracic vertebra.
5. Right bronchial vein, near the terminal end of the azygos vein.
6. Several oesophageal, mediastinal, pericardial veins.
7. When the azygos vein begins as lumbar azygos vein the common trunk formed by the union of the right ascending lumbar vein and right subcostal vein is the largest tributary.

CLINICAL ANATOMY

In superior vena caval obstruction, the vein is the main channel which transmits the blood from the upper half of the body to either the unobstructed portion of the superior vena cava or to the inferior vena cava.

HEMIAZYGOS VEIN

Hemiazygos vein is also called the inferior hemiazygos vein. It is the mirror image of the lower part azygos vein. It may originate either from the surface of the left renal vein, or may be formed by the union of the left ascending lumbar and left subcostal veins.

Course

Hemiazygos vein pierces the left crus of the diaphragm, ascends on the left side of the vertebra overlapped by the aorta. At the level of eighth thoracic vertebra, it turns to the right, passes behind the oesophagus and the thoracic duct, and joins the azygos vein (Fig. 14.8).

Tributaries

(i) Left ascending lumbar vein, (ii) left subcostal vein, and (iii) ninth to eleventh left posterior intercostal veins.
**ACCESSORY HEMIAZYGOS VEIN**

Accessory hemiazygos vein is also called the superior hemiazygos vein. It is the mirror image of the upper part of the azygos vein.

**Course**

Accessory hemiazygos vein begins at the medial end of the fourth or fifth intercostal space, and descends on the left side of the vertebral column. At the level of eighth thoracic vertebra it turns to the right, passes behind the aorta and the thoracic duct, and joins the azygos vein.

Sometimes the hemiazygos and accessory hemiazygos veins join together to form a common trunk which opens into the azygos vein.

**Tributaries**

(i) Fifth to eighth left posterior intercostal veins, and (ii) sometimes the left bronchial veins.

---

**THE THORACIC SYMPATHETIC TRUNK**

The thoracic sympathetic trunk is a ganglionated chain situated one on each side of the thoracic vertebral column. Superiorly it is continuous with the cervical part of the chain and inferiorly with the lumbar part (Figs 14.12, 14.13).

Theoretically the chain bears 12 ganglia corresponding to the 12 thoracic nerves. However, the number of the ganglia is often reduced to 10 or 11 due to fusion of adjacent ganglia with one another.
The first thoracic ganglion is commonly fused with the inferior cervical ganglion to form the cervicothoracic, or stellate ganglion. The second thoracic ganglion is occasionally fused with the first. The remaining thoracic ganglia generally lie at the levels of the corresponding intervertebral discs and the intercostal nerves. The portion of the chain between two ganglia may be very slender; and at other times it may be double.

**Course and Relations**

The chain crosses the neck of the first rib, the heads of the second to tenth ribs, and bodies of the eleventh and twelfth thoracic vertebrae. The whole chain descends in front of the posterior intercostal vessels and the intercostal nerves, and passes deep to the medial arcuate ligament to become continuous with the lumbar part of the sympathetic chain.

**Branches**

*Lateral Branches for the Limbs and Body Wall*

Each ganglion is connected with its corresponding spinal nerve by two rami, the white (preganglionic) and grey (postganglionic) rami communicans. The white ramus is distal to the grey ramus, the two rami may fuse to form a single 'mixed' ramus.

*Medial Branches for the Viscera*

(a) Medial branches from the upper 5 ganglia are postganglionic and get distributed to the heart, the
great vessels, the lungs and the oesophagus, through:

(i) Pulmonary branches to the pulmonary plexuses.
(ii) Cardiac branches to the deep cardiac plexus.
(iii) Aortic branches to thoracic aortic plexus.
(iv) Oesophageal branches which join the oesophageal plexus.

(b) Medial branches from the lower 7 ganglia are preganglionic and form three splanchnic nerves.

(i) The greater splanchnic nerve is formed by 5 roots from ganglia 5 to 9. It descends obliquely on the vertebral bodies, pierces the crus of the diaphragm, and ends (in the abdomen) mainly in the coeliac ganglion, and partly in the aorticorenal ganglion and the suprarenal gland.

(ii) The lesser splanchnic nerve is formed by two roots from ganglia 10 and 11. Its course is similar to that of the greater splanchnic nerve. It pierces the crus of the diaphragm, and ends in the coeliac ganglion (Fig. 14.12).

(iii) The least (lowest) splanchnic nerve (renal nerve) is tiny and often absent. It arises by one root from ganglion 12. It either pierces the corresponding crus of the diaphragm, or passes behind the medial arcuate ligament (with the main sympathetic chain) and ends in the renal plexus.
The spongy lungs occupying a major portion of thoracic cavity are enveloped in a serous cavity — the pleural cavity. There is always slight negative pressure in this cavity. During inspiration the pressure becomes more negative, and air is drawn into the lungs covered with its visceral and parietal layers. Visceral layer is inseparable from the lung and is supplied by the same arteries, veins and nerves as lungs. In a similar fashion, the parietal pleura sincerely follows the walls of the thoracic cavity with cervical, costal, diaphragmatic and mediastinal parts. Pleural cavity limits the expansion of the lungs.

THE PLEURA

Introduction

Like the peritoneum, the pleura is a serous membrane which is lined by mesothelium (flattened epithelium). There are two pleural sacs, one on either side of the mediastinum. Each pleural sac is invaginated from its medial side by the lung, so that it has an outer layer, the parietal pleura, and an inner layer, the visceral or pulmonary pleura. The two layers are continuous with each other around the hilum of the lung, and enclose between them a potential space, the pleural cavity (Fig. 15.3). In some diseases, the pleural cavity may get filled with air, fluid, blood, or pus. These conditions are called pneumothorax, pleural effusion, haemothorax or empyema respectively.

■■■■■ DISSECTION (■■■■■)

Divide the manubrium stern transversely immediately inferior to its junction with the first costal cartilage. Cut through the parietal pleura in the first intercostal space on both sides as far back as possible. Carry the cut inferiorly through
the second and lower ribs or costal cartilages from the posterior end of pleural incision to the level of the xiphisternal joint.

Lift the inferior part of manubrium and body of sternum with ribs and costal cartilages and reflect it towards abdomen. Identify the pleura extending from the back of sternum on to the mediastinum to the level of lower border of heart. Note the smooth surface of pleura where it lines the thoracic wall and covers the lateral aspects of mediastinum. Trace the reflection of parietal pleura on the skeleton.

Remove the pleura and the endothoracic fascia from the back of sternum and costal cartilages which is reflected towards abdomen. Identify the transversus thoracis muscle and internal thoracic vessels. Note the origin of diaphragm from the xiphoid process and divide it. Identify the course and branches of intercostal nerve again. Trace the nerve medially superficial to the internal thoracic vessels.

Pull the lung laterally from the mediastinum and find its root with the pulmonary ligament extending downwards from it. Cut through the structures, i.e. bronchus/bronchi, pulmonary vessels, nerves, comprising its root from above downwards close to the lung. Remove the lung on each side. Be careful not to injure the lung or your hand from the cut ends of the ribs.

Identify the phrenic nerve with accompanying blood vessels anterior to the root of the lung. Give a longitudinal incision through the pleura only parallel to and on each side of the phrenic nerve. Strip the pleura posterior to the nerve backwards to the intercostal spaces. Pull the anterior flap forwards to reveal part of the pericardium with the heart. Identify the following structures seen through the pleura.
Right side

1. Bulge of the heart and pericardium antero-inferior to the root of the lung (Fig. 15.1).
2. A longitudinal ridge formed by right brachio-cephalic vein down to first costal cartilage and by superior vena cava up to the bulge of the heart.
3. A smaller longitudinal ridge formed by inferior vena cava formed between the heart and the diaphragm.
4. Phrenic nerve with accompanying vessels forming a vertical ridge on these two venae cavae passing anterior to root of the lung.
5. Vena azygos arching over root of the lung to enter the superior vena cava.
6. Trachea and oesophagus posterior to the phrenic nerve and superior vena cava.
7. Right vagus nerve descending postero-inferiorly across the trachea, behind the root of the lung.
8. Bodies of the thoracic vertebrae behind oesophagus with posterior intercostal vessels and azygos vein lying over them.
9. Sympathetic trunk on the heads of the upper ribs and on the sides of the vertebral bodies below this, anterior to the posterior intercostal vessels and intercostal nerves.

Left Side

1. Bulge of the heart (Fig. 15.2).
2. Root of lung posterosuperior to it.
3. Descending aorta between (1) and (2) in front and vertebral column behind.
4. Arch of aorta over the root of the lung.
5. Left common carotid and left subclavian arteries passing superiorly from the arch of aorta.
6. Phrenic and vagus nerves descending between these vessels and the lateral surface of the aortic arch.
7. Sympathetic trunk same as on right side.

Identify longitudinally running sympathetic trunk on the posterior part of thoracic cavity. Find delicate greater and lesser splanchnic nerves arising from the trunk on the medial side. Look carefully for grey and white rami communicans between the intercostal nerve and the ganglia on the sympathetic trunk. Trace the intercostal vessels above the intercostal nerve. The order being vein, artery and nerve (VAN). On the right side identify and follow one of the divisions of trachea to the lung root and the superior and inferior venae cavae till the pericardium.
Fig. 15.2: Mediastinum as seen from the left side.
On the left side of thoracic cavity dissect the arch of aorta. Identify the superior cervical cardiac branch of the left sympathetic trunk and the inferior cervical cardiac branch of the left vagus on the arch of the aorta between the vagus nerve posteriorly and phrenic nerve anteriorly.

The cavity of the thorax contains the right and left pleural cavities which are completely invaginated and occupied by the lungs. The right and left pleural cavities are separated by a thick median partition called the mediastinum. The heart lies in the mediastinum.

**The Pulmonary Pleura**

"The pulmonary pleura covers the surfaces and fissures of the lung, except at the hilum and along the attachment of the pulmonary ligament where it is..."
continuous with the parietal pleura. It is firmly adherent to the lung and cannot be separated from it.

The Parietal Pleura

The parietal pleura is thicker than the pulmonary pleura, and is subdivided into four parts: (i) costal, (ii) diaphragmatic, (iii) mediastinal, and (iv) cervical (Figs 15.3, 15.4).

The **costal pleura** lines the thoracic wall comprises ribs and intercostal spaces to which it is loosely attached by a layer of areolar tissue called the endothoracic fascia. The **mediastinal pleura** lines the corresponding surface of the mediastinum. It is reflected over the root of the lung and becomes continuous with the pulmonary pleura around the hilum. The **cervical pleura** extends into the neck, nearly 5 cm above the first costal cartilage and 2.5 cm above the medial one-third of the clavicle, and covers the apex of the lung (Fig. 12.7). It is covered by the suprapleural membrane. It is related anteriorly to the subclavian artery and the scalenus anterior; posteriorly to the neck of the first rib and structures lying over it; laterally to the scalenus medius; and medially to the large vessels of the neck (Fig. 12.7).

Diaphragmatic pleura lines the superior aspect of diaphragm. It covers the base of the lung and gets continuous with mediastinal pleura medially and costal pleura laterally.
The Pulmonary Ligament

The parietal pleura surrounding the root of the lung extends downwards beyond the root as a fold called the pulmonary ligament. The fold contains a thin layer of loose areolar tissue with a few lymphatics. Actually it provides a dead space into which the pulmonary veins can expand during increased venous return as in exercise. The lung roots can also descend into it with the descent of the diaphragm (Fig. 15.5).

---

Surface Marking of the Pleura

The **cervical pleura** is represented by a curved line forming a dome over the medial one-third of the clavicle with a height of about 2.5 cm above the bone (Fig. 15.9, 16.5).

The **anterior margin**, the costomediastinal line of pleural reflection is as follows: On the right side it extends from the sternoclavicular joint downwards and medially to the midpoint of the sternal angle. From here it continues vertically downwards to the midpoint of the xiphisternal joint. On the left side, the line follows the same course up to the level of the fourth costal cartilage. It then arches outwards and descends along the sternal margin up to the sixth costal cartilage.

The **inferior margin**, or the costodiaphragmatic line of pleural reflection passes laterally from the lower limit of its anterior margin, so that it crosses the eighth rib in the midclavicular line, the tenth rib in the midaxillary line, and the twelfth rib at the lateral border of the sacrospinalis muscle. Further it passes horizontally to the lower border of the twelfth thoracic vertebra, 2 cm lateral to the upper border of the twelfth thoracic spine.

Thus the pleurae descend below the costal margin at three places, at the right xiphiacostal angle, and at the right and left costovertebral angles below the twelfth rib behind the upper poles of the kidneys. The latter fact is of surgical importance in exposure of the kidney. The pleura may be damaged at this site (Figs 15.6, 15.9).
The posterior margins of the pleura pass from a point 2 cm lateral to the twelfth thoracic spine to a point 2 cm lateral to the seventh cervical spine. The costal pleura becomes the mediastinal pleura along this line.

Nerve Supply of the Pleura

The parietal pleura develops from the somatopleuric layer of the lateral plate mesoderm, and is supplied by the somatic nerves. These are the intercostal and phrenic nerves. The parietal pleura is pain sensitive. The costal and peripheral parts of the diaphragmatic pleurae are supplied by the intercostal nerves, and the mediastinal pleura and central part of the diaphragmatic pleurae by the phrenic nerves. The pulmonary pleura develops from the splanch-nopleuric layer of the lateral plate mesoderm, and is supplied by autonomic nerves. The sympathetic nerves are derived from second to fifth spinal segments while parasympathetic nerves are drawn from the vagus nerve. The nerves accompany the bronchial vessels. This part of the pleura is not sensitive to pain.

Blood Supply and Lymphatic Drainage of the Pleura

The parietal pleura is a part and parcel of the thoracic wall. Its blood supply and lymphatic drainage are, therefore, the same as that of the body wall. It is thus supplied by intercostal, internal thoracic and musculophrenic arteries.

The veins drain mostly into the azygos and internal thoracic veins. The lymphatics drain into the intercostal, internal mammary, posterior mediastinal and diaphragmatic nodes.

CLINICAL ANATOMY

Aspiration of any fluid from the pleural cavity is called paracentesis thoracis. It is usually done in the eighth intercostal space in the midaxillary line. The needle is passed through the lower part of the space to avoid injury to the principal neurovascular bundle.

Some clinical conditions associated with the pleura are as follows:

1. Pleurisy. This is inflammation of the pleura. It may be dry, but often it is accompanied by
bronchial veins. It is drained by the bronchopulmonary lymph nodes.

collection of fluid in the pleural cavity. The condition is called the pleural effusion.
1. **Pneumothorax.** Presence of air in the pleural cavity.
2. **Haemothorax.** Presence of blood in the pleural cavity.
3. **Hydropneumothorax.** Presence of both fluid and air in the pleural cavity.
4. **Empyema.** Presence of pus in the pleural cavity.
The lungs occupying major portions of the thoracic cavity leave little space for the heart, which excavates more of the left lung. The two lungs hold the heart tight between them, providing it the protection it rightly deserves. There are ten bronchopulmonary segments in both the lungs.

Introduction
The lungs are a pair of respiratory organs situated in the thoracic cavity. Each lung invaginates the corresponding pleural

Fig. 16.1: The trachea and lungs as seen from the front.
cavity. The right and left lungs are separated by the mediastinum.

The lungs are spongy in texture. In the young, the lungs are brown or grey in colour. Gradually, they become mottled black because of the deposition of inhaled carbon particles. The right lung weighs about 700 g; it is about 50-100 g heavier than the left lung.

Identify the lungs by the thin anterior border, thick posterior border, conical apex, wider base, medial surface with hilum and costal surface with impressions of the ribs and intercostal spaces. In addition, the right lung is distinguished by the presence of three lobes whereas left lung comprises two lobes only. On the mediastinal part of the medial surface of right lung identify two bronchi—the eparterial and hyparterial bronchi, with bronchial vessels and posterior pulmonary plexus, the pulmonary artery between the two bronchi on an anterior plane. The upper pulmonary vein is situated still on an anterior plane while the lower pulmonary vein is identified below the bronchi. The impressions on the right lung are of superior vena cava, inferior vena cava, right ventricle. Behind the root of lung are the impressions of vena azygos and oesophagus.
Hilum of the left lung shows the single bronchus situated posteriorly, with bronchial vessels and posterior pulmonary plexus. The pulmonary artery lies above the bronchus. Anterior to the bronchus is the upper pulmonary vein, while the lower vein lies below the bronchus. The mediastinal surface of left lung has the impression of left ventricle, ascending aorta. Behind the root of the left lung are the impressions of descending thoracic aorta while oesophagus leaves an impression in the lower part only.

Features

Each lung is conical in shape (Fig. 16.1). It has: (1) an apex at the upper end; (2) a base resting on the diaphragm; (3) three borders, i.e. anterior, posterior and inferior; and (4) two surfaces, i.e. costal and medial. The medial surface is divided into vertebral and mediastinal parts.
The apex is blunt and lies above the level of the anterior end of the first rib. It reaches nearly 2.5 cm above the medial one-third of the clavicle, just medial to the suprACLAVICULAR fossa. It is covered by the cervical pleura and by the suprapleural membrane, and is grooved by the subclavian artery on the medial side and in front.

The base is semilunar and concave. It rests on the diaphragm which separates the right lung from the right lobe of the liver, and the left lung from the left lobe of the liver, the fundus of the stomach, and the spleen.

The anterior border is very thin (Figs 16.2, 16.3). It is shorter than the posterior border. On the right side it is vertical and corresponds to the anterior or costomediastinal line of pleural reflection. The anterior border of the left lung shows a wide cardiac notch below the level of the fourth costal cartilage. The heart and pericardium are uncovered by the lung in the region of this notch.

The posterior border is thick and ill defined. It corresponds to the medial margins of the heads of the ribs. It extends from the level of the seventh cervical spine to the tenth thoracic spine.

The inferior border separates the base from the costal and medial surfaces.

The costal surface is large and convex. It is in contact with the costal pleura and the overlying thoracic wall.

The medial surface is divided into a posterior vertebral part, and an anterior or mediastinal part. The vertebral part is related to the vertebral bodies, intervertebral discs, the posterior intercostal vessel and the splanchnic nerves. The mediastinal part is related to the mediastinal septum, and shows cardiac impression, the hilum and a number of other impressions which differ on the two sides. Various relations of the mediastinal surfaces of the two lungs are listed in Table 16.1.

Fig. 16.3: Impressions on the mediastinal surface of the left lung.
Fissures and Lobes of the Lungs

The right lung is divided into 3 lobes (upper, middle and lower) by two fissures, oblique and horizontal. The left lung is divided into two lobes by the oblique fissure (Fig. 16.1).

The *oblique fissure* cuts into the whole thickness of the lung, except at the hilum. It passes obliquely downwards and forwards, crossing the posterior border about 6 cm below the apex and the inferior border about 5 cm from the median plane. Due to the oblique plane of the fissure the lower lobe is more posterior and the upper and middle lobe more anterior. In the right lung, the *horizontal fissure* passes from the anterior border up to the oblique fissure and separates a wedge-shaped middle lobe from the upper lobe. The fissure runs horizontally at the level of the fourth costal cartilage and meets the oblique fissure in the midaxillary line. The tongue-shaped projection of the left lung below the cardiac notch is called the *lingula*. It corresponds to the middle lobe of the right lung.

The number of lobes may vary in either lung. The right lung may have only two lobes, upper and lower and the left lung may have three lobes. Accessory lobes may also be present.

The lungs expand maximally in the inferior direction because movements of the thoracic wall and diaphragm are maximal towards the base of the lung. The presence of the oblique fissure of each lung allows a more uniform expansion of the whole lung.
Root of the Lung

Root of the lung is a short, broad pedicle which connects the medial surface of the lung to the mediastinum. It is formed by structures which either enter or come out of the lung at the hilum. The roots of the lungs lie opposite the bodies of the fifth, sixth and seventh thoracic vertebrae.

Contents

The root is made up of the following structures:

1. Principal bronchus on the left side, and eparterial and hyparterial bronchi on right side.
2. One pulmonary artery.
3. Two pulmonary veins, superior and inferior.
4. Bronchial arteries, one on the right side and two on the left side.
5. Bronchial veins.
6. Anterior and posterior pulmonary plexuses of nerves.
7. Lymphatics of the lung.
8. Bronchopulmonary lymph nodes.
9. Areolar tissue.

Arrangement of Structures in the Root (Fig. 16.4)

A. From before backwards. It is similar on the two sides:

Surface Marking of the Lung
The apex of the lung coincides with the cervical I pleura, and is represented by a line convex upwards I rising 2.5 cm above the medial one-third of the clavicle (Fig. 16.5).

The anterior border of the right lung corresponds very closely to the anterior margin or costomedia- j stinal line of the pleura and is obtained by joining: (i) a point at the sternoclavicular joint, (ii) another point in the median plane at the sternal angle, and (iii) a third point in the median plane just above the xiphisternal joint. The anterior border of the left lung corresponds to the anterior margin of the pleura up to the level of the fourth costal cartilage. In the lower part, it presents a cardiac notch of variable size. From the level of the fourth cartilage it passes laterally for 3.5 cm from the sternal margin, and then curves downwards and medially to reach the sixth costal cartilage 4 cm from the median plane. In the region of the cardiac notch, the pericardium is covered only by a double layer of pleura. The area of the cardiac notch is dull on percussion and is called the area of superficial cardiac dullness.

The lower border of each lung lies two ribs higher than the pleural reflection. It crosses the sixth rib in the midaclavicular line, the eighth rib in the midaxillary line, the tenth rib at the lateral border of the erector spinae, and ends 2 cm lateral to the tenth thoracic spine.

The posterior border coincides with the posterior margin of the pleural reflection except that its lower end lies at the level of the tenth thoracic spine.
The oblique fissure can be drawn by joining: (i) a point 2 cm lateral to the third thoracic spine, (ii) another point on the fifth rib in the midaxillary line, and (iii) a third point on the sixth costal cartilage 7.5 cm from the median plane.

The horizontal fissure is represented by a line joining: (i) a point on the anterior border of the right lung at the level of the fourth costal cartilage, and (ii) a second point on the fifth rib in the midaxillary line.
Differences Between the Right and Left Lungs

These are given in Table 16.2.

Arterial Supply of the Lungs

The bronchial arteries supply nutrition to the bronchial tree and to the pulmonary tissue. These are

Arterial Supply of the Lungs

The bronchial arteries supply nutrition to the bron-
small arteries that vary in number, size and origin, but usually they are as follows.

(1) On the right side there is one bronchial artery which arises either from the third posterior intercostal artery or from the upper left bronchial artery.

(2) On the left side there are two bronchial arteries both of which arise from the descending thoracic aorta, the upper opposite fifth thoracic vertebra and the lower just below the left bronchus.

Deoxygenated blood is brought to the lungs by the pulmonary arteries and oxygenated blood is returned to the heart by the pulmonary veins.

There are precapillary anastomoses between bronchial and pulmonary arteries. These connections enlarge when any one of them is obstructed in disease.

**Venous Drainage of the Lungs**

The venous blood from the first one or two divisions of the bronchi is carried by bronchial veins. Usually there are two bronchial veins on each side. The right bronchial veins drain into the azygos vein. The left bronchial veins drain either into the left superior intercostal vein or into the hemiazygos vein.

The greater part of the venous blood from the lungs is drained by the pulmonary veins.
Lymphatic Drainage of the Lungs

There are two sets of lymphatics, both of which drain into the bronchopulmonary nodes.

1. Superficial vessels drain the peripheral lung tissue lying beneath the pulmonary pleura. The vessels pass round the borders of the lung and margins of the fissures to reach the hilum.

2. Deep lymphatics drain the bronchial tree, the pulmonary vessels and the connective tissue septa. They run towards the hilum where they drain into the bronchopulmonary nodes.

The superficial vessels have numerous valves: the deep vessels have only a few valves or no valves at all. Though there is no free anastomosis between the superficial and deep vessels some connections exist which can open up, so that lymph can flow from the deep to the superficial lymphatics when the deep vessels are obstructed in disease of the lungs or of the lymph nodes.

Nerve Supply

1. Parasympathetic nerves are derived from the vagus. These fibres are: (i) motor to the bronchial muscles, and on stimulation cause bronchospasm; (ii) secretomotor to the mucous glands of the bronchial tree; and (iii) sensory. The sensory fibres are responsible for the stretch reflex of the lungs, and for the cough reflex.

2. Sympathetic nerves are derived from second to fifth spinal segments. These are inhibitory to the smooth muscle and glands of the bronchial tree. That is how sympathomimetic drugs, like adrenalin, cause bronchodilatation and relieve symptom of bronchial asthma.

Both parasympathetic and sympathetic nerves first form anterior and posterior pulmonary plexuses situated in front of and behind the lung roots: from the plexuses nerves are distributed to the lungs along the blood vessels and bronchi.

Dissection

Dissect the principal bronchus into the left lung. Remove the pulmonary tissue and follow the main bronchus till it is seen to divide into two lobar bronchi. Try to dissect till these divide into the segmental bronchi.

Bronchial Tree

The trachea divides at the level of the lower border of the fourth thoracic vertebra into two primary principal bronchi, one for each lung. The right principal bronchus is 2.5 cm long. It is shorter, wider and more in line with the trachea than the left principal bronchus. Inhaled particles, therefore, tend to pass more frequently to the right lung, with the result that infections are more common on the right side than on the left. The left principal bronchus is 5 cm. It is longer, narrower and more oblique than the right bronchus.

Each principal bronchus enters the lung through the hilum, and divides into secondary lobar bronchi, 1 one for each lobe of the lungs. Thus there are three lobar bronchi on the right side, and only two on the 1 left side. Each lobar bronchus divides into tertiary or segmental bronchi, one for each bronchopulmonary segment; which are 10 on the right side and 10 on the left side. The segmental bronchi divide repeatedly to form very small branches called terminal bronchioles. Still smaller branches are called respiratory bronchioles.

Each respiratory bronchiole aerates a small part of the lung known as a pulmonary unit. The respiratory bronchiole ends in microscopic passages which are termed: (i) alveolar ducts, (ii) atria, (iii) air sacculles, and (iv) pulmonary alveoli. Gaseous exchanges take place in the alveoli (Fig. 16.6).

Bronchopulmonary Segments

Definition. These are well-defined sectors of the lung, each one of which is aerated by a tertiary or segmental bronchus. Each segment is pyramidal in shape with its apex directed towards the root of the lung (Fig. 16.7).

The most widely accepted classification of segments is given in Table 16.3. There are 10 segments on the right side and 10 on the left (Figs 16.8, 16.9).

Intersegmental planes. Each segment is surrounded by connective tissue which is continuous on the surface with pulmonary pleura. Thus the bronchopulmonary segments are independent respiratory units.

**Fig. 16.7:** Diagram of a bronchopulmonary segment.

**Fig. 16.8:** Bronchopulmonary segments of the lungs.
The connective tissue septa between adjoining segments form intersegmental planes which are crossed by the pulmonary veins and occasionally by the pulmonary arteries. During removal of a segment or segmental resection, the surgeon works along the pulmonary veins to isolate a particular segment.

Relation to pulmonary artery. The branches of the pulmonary artery accompany the bronchi. The artery
lies dorsolateral to the bronchus. Thus each segment has its own separate artery (Fig. 16.10).

Relation to pulmonary vein. The pulmonary veins do not accompany the bronchi or pulmonary arteries. They run in the intersegmental planes. Thus each segment has more than one vein and each vein drains more than one segment. Near the hilum the veins are ventromedial to the bronchus.
It should be noted that the bronchopulmonary segment is not a bronchovascular segment because it does not have its own vein.

There is considerable variation in the above pattern of bronchi, arteries and veins: the veins being more variable than arteries, and the arteries more variable than the bronchi.

Histology of Trachea and Lung

Trachea and extrapulmonary bronchi have pseudo-stratified ciliated columnar epithelium with goblet cells. Lamina propria contains connective tissue and ducts of glands present in submucosa. No muscularis mucosae is present
Submucosa contains mucous and serous acini, Outermost is musculocartilaginous layer with 'C'-shaped hyaline cartilage and smooth muscle fibres joining the two ends of 'C'-shaped cartilage. Outermost is connective tissue.

Intrapulmonary bronchus: Epithelium is same as in trachea. The epithelium is thrown into folds. Lamina propria is same as in trachea. The lamina propria is surrounded on all sides by thin sheet of smooth muscle fibres. Outside the muscle layer are small pieces of cartilage with glands in between these pieces. Outermost is the connective tissue. ^Terminal bronchiole is lined by columnar epithelium with no cilia or goblet cells. Smooth muscles surround it all around. No cartilage or glands are seen. Connective tissue is seen outside.) /Respiratory bronchiole is lined by cuboidal cells. There are outpocketing of alveoli. Smooth muscle' fibres and connective tissue surround it. No glands, or cartilage is seen. Alveoli are lined by squamous cells. Few cuboidal cells producing surfactant are seen. No muscle, no gland, no cartilage seen. Interalveolar connective tissue contains capillaries.

Development of Respiratory System

During fourth week of embryonic life the tracheobronchial or lung bud appears as a diverticulum from the ventral wall of the foregut. As this bud descends downwards it gets separated from oesophagus by oesophagotracheal septum. The two, however, maintain communication at the level of laryngeal inlet.

The lung bud forms trachea and two bronchial buds one on each side of trachea. Each bud forms
right and left principal bronchi. The right one divides into three and the left one into two lobar bronchi.

The developing lung buds invaginate and expand into pericardioperitoneal canals, the primitive pleural cavities and get covered by visceral and parietal pleura.

The bronchi divide into 18 generations before birth and six generations after birth to reach the final stage.

Maturation of lung occurs through pseudo-glandular period (5-16 weeks), canalicular period (16-26 weeks), terminal sac period (26 weeks to birth) and alveolar period (eighth month to childhood).

Epithelial lining of trachea, bronchi till alveoli including the glands are endodermal in origin. The cartilages, muscles, connective tissue develop from splanchnic mesoderm around the foregut.

**CLINICAL ANATOMY**

1. Usually the infection of a segment remains restricted to it, although some infections like tuberculosis may spread from one segment to another.

2. Segments are no barriers to the spread of bronchogenic carcinoma.

3. Knowledge of the detailed anatomy of the bronchial tree helps considerably in:
   (i) Surgical removal of a segment or segmental resection.
   (ii) Drainage of lung abscess or bronchiectasis by making the patient adopt a particular posture called postural drainage.
   (iii) Visualizing the interior of the bronchi through an instrument passed through the mouth and trachea. The instrument is called a bronchoscope and the procedure is called bronchoscopy.
   (iv) In understanding why abscesses are more common in some segments like the posterior segment of the right upper lobe, and the apical segment of the right lower lobe.
Mediastinum is the middle space left in the thoracic cavity in between the lungs. Its most important content is the heart enclosed in the pericardium in the middle part of the inferior mediastinum or the middle mediastinum. Above it, lies superior mediastinum. Anterior and posterior to the heart are anterior mediastinum and posterior mediastinum respectively.

Introduction

The mediastinum is the median septum of the thorax between the two lungs. It includes the mediastinal pleurae (Figs 15.7, 15.8).
DISSECTION

Reflect the upper half of manubrium sterni upwards and study the boundaries and contents of superior and three divisions of the inferior mediastinum.

**Boundaries**

- **Anteriorly**: Sternum
- **Posteriorly**: Vertebral column
- **Superiorly**: Thoracic inlet
- **Interiorly**: Diaphragm
- **On each side**: Mediastinal pleura.

**Divisions**

For descriptive purposes the mediastinum is dividei into the *superior mediastinum* and the *inferior mediastinum*. The inferior mediastinum is further dividei into the *anterior, middle and posterior mediastinum* (Fig. 17.1).

The superior mediastinum is separated from th inferior by an imaginary plane passing through th sternal angle (anteriorly) and the lower border of th body of the fourth thoracic vertebra posteriorly. Th
inferior mediastinum is subdivided into three parts by the pericardium. The area in front of the pericardium is the anterior mediastinum. The area behind the pericardium is the posterior mediastinum. The pericardium and its contents form the middle mediastinum.

SUPERIOR MEDIASTINUM

Boundaries

Anteriorly : Manubrium sterni Posteriorly : Upper four thoracic vertebrae Superiorly : Plane of the thoracic inlet Interiorly : An imaginary plane passing through the sternal angle in front, and the lower border of the body of the fourth thoracic vertebra behind. On each side : Mediastinal pleura.
Contents

1. Trachea and oesophagus.
2. Muscles: Origins of: (i) sternohyoid and (ii) sternothyroid, and (iii) lower ends of longus colli.
3. Arteries: (i) Arch of aorta, (ii) brachiocephalic artery, (iii) left common carotid artery, and (iv) left subclavian artery (Fig. 17.2).
4. Veins: (i) Right and left brachiocefalic veins, (ii) upper half of the superior vena cava, and (iii) left superior intercostal vein.
5. Nerves: (i) Vagus, (ii) phrenic, (iii) cardiac nerves, of both sides, and (iv) left recurrent laryngeal nerve.
6. Thymus.
7. Thoracic duct.

1. The prevertebral layer of the deep cervical fascia extends to the superior mediastinum, and is attached to the fourth thoracic vertebra. An infection present in the neck behind this fascia can pass down into the superior mediastinum but not lower down.

The pretracheal fascia of the neck also extends to the superior mediastinum, where it blends with the arch of the aorta. Neck infections between the pretracheal and prevertebral fasciae can spread into the superior mediastinum, and through it into the posterior mediastinum. Thus mediastinitis can result from infections in the neck.

2. In the superior mediastinum, all large veins are on the right side and the arteries on the left side. During increased blood flow veins expand enormously, while the large arteries do not expand at all. Thus there is much 'dead space' on the right side and it is into this space that tumours or fluids of the mediastinum tend to project.

8. Lymph nodes: Paratracheal, brachiocephalic, and tracheobronchial.

INFERIOR MEDIASTINUM

The inferior mediastinum is divided into anterior, middle and posterior mediastina. These are as under:

Anterior Mediastinum

Anterior mediastinum is a very narrow space in front of the pericardium, overlapped by the thin anterior borders of both lungs. It is continuous through the superior mediastinum with the pretracheal space of the neck.

Boundaries

Anteriorly: Body of sternum.
Posteriorly: Pericardium.
**Superiorly** : Imaginary plane separating the superior mediastinum from the inferior mediastinum. **Inferiorly** : Superior surface of diaphragm. **On each side** : Mediastinal pleura.

**Contents**

(i) Sternopericardial ligaments, (ii) lymph nodes with lymphatics, (iii) small mediastinal branches of the internal thoracic artery, (iv) the lowest part of the thymus, and (v) areolar tissue.

**Middle Mediastinum**

Middle mediastinum is occupied by the pericardium and its contents, along with the phrenic nerves and the pericardiophrenic vessels.

**Boundaries**

**Anteriorly** : Posterior surface of sternum **Posteriorly** : Oesophagus, descending thoracic aorta, azygos vein On each side - Mediastinal pleura.

**Contents**

1. **Heart** enclosed in pericardium.
2. **Arteries** : (i) Ascending aorta, (ii) pulmonary trunk, and (iii) two pulmonary arteries.
3. **Veins** : (i) Lower half of the superior vena cava, (ii) terminal part of the azygos vein, and (iii) right and left pulmonary veins (Fig. 17.3).
4. **Nerves** : (i) Phrenic, and (ii) deep cardiac plexus.
5. **Lymph nodes** : Tracheobronchial nodes.
6. *Tubes*: (i) Bifurcation of trachea, and (ii) the right and left principal bronchi.

**Posterior Mediastinum**

**Boundaries**

*Anteriorly*: (i) Pericardium, (ii) bifurcation of trachea, (iii) pulmonary vessels, and (iv) posterior part of the upper surface of the diaphragm.

*Posteriorly*: Lower eight thoracic vertebrae and intervening discs.

On each side: Mediastinal pleura.

**Contents**

1. Oesophagus (Fig. 17.4).
3. Veins: (i) Azygos vein, (ii) hemiazygos vein, and (iii) accessory hemiazygos vein.
4. Nerves: (i) Vagi, and (ii) splanchnic nerves, greater, lesser and least, arising from the lower eight thoracic ganglia of the sympathetic chain.
5. Lymph nodes and lymphatics: (i) Posterior mediastinal lymph nodes lying alongside the aorta, and (ii) the thoracic duct (Fig. 17.4).
CLINICAL ANATOMY

1. The posterior mediastinum is continuous through the superior mediastinum with the neck between the pretracheal and prevertebral layers of the cervical fascia. This region of the neck includes the retropharyngeal space, spaces on each side of the trachea and oesophagus, the space between these tubes and the carotid sheaths. Infections leading to fluid collections from these spaces can spread to the superior and posterior mediastina.

2. Compression of mediastinal structures by any tumour gives rise to a group of symptoms known as 'mediastinal syndrome'. The common symptoms are as follows.
   (i) Obstruction of the superior vena cava gives rise to engorgement of veins in the upper half of the body.
   (ii) Pressure over the trachea causes dyspnoea.
   (iii) Pressure on the oesophagus causes dysphagia.
   (iv) Pressure or the left recurrent laryngeal nerve gives rise to hoarseness of voice.
   (v) Pressure on the phrenic nerve causes paralysis of the diaphragm on that side.
   (vi) Pressure on the intercostal nerves gives rise to pain in the area supplied by them. It is called intercostal neuralgia.
   (vii) Pressure on the vertebral column may cause erosion of the vertebral bodies. The common causes of mediastinal syndrome are bronchogenic carcinoma, Hodgkin's disease causing enlargement of the mediastinal lymph nodes, aneurysm or dilatation of the aorta, etc.
Pericardium, comprising fibrous and serous layers, encloses the heart pulsating from 'womb to tomb'. It limits its movements.

Heart is a vital organ, pumping blood to the entire body. Its pulsations are governed by the brain through various nerves. Since heart beat is felt or seen against the chest wall, it appears to be more active than the quiet brain controlling it. That is why there are so many songs on the heart and none on the brain. Meditation, yoga and exercise help in regulating the heart beat through the brain.

THE PERICARDIUM

The pericardium is a fibroserous sac which encloses the heart and the roots of the great vessels. It is situated in the middle mediastinum. It consists of the fibrous pericardium and the serous pericardium (Figs 18.1, 18.2).

Fibrous pericardium encloses the heart and fuses with the vessels which enter/leave the heart. Heart is situated within the fibrous and serous pericardial
sacs. As heart develops, it invaginates itself into the serous sac, without causing any breach in its continuity, the last part to enter is the region of atria, from where the visceral pericardium is reflected as the parietal pericardium. Thus parietal layer of serous pericardium gets adherent to the inner surface of fibrous pericardium, while the visceral layer of serous pericardium gets adherent to the outer layer of heart and forms its epicardium.

**DISSECTION**

Make a vertical cut through each side of the pericardium immediately anterior to the line of the phrenic nerve. Join the lower ends of these two incisions by a transverse cut approximately 1 cm above the diaphragm. Turn the flap of pericardium upwards and, examine the pericardial cavity. See that the turned flap comprises fibrous and parietal layer of visceral pericardium. The pericardium enclosing the heart is its visceral layer.
Pass a probe from (lie right side behind the ascending aorta and pulmonary trunk till it appears on the left just to the right of left atrium. This probe is in the transverse sinus of the pericardium. Lift the apex of the heart upwards. Put a finger behind the left atrium into a cul-de-sac, bounded to the right and below by inferior vena cava and above and to left by lower left pulmonary vein. This is the oblique sinus of the pericardium.

Define the borders, surfaces, grooves, apex and base of the heart.

**FIBROUS PERICARDIUM**

Fibrous pericardium is a conical sac made up of fibrous tissue. The parietal layer of serous pericardium is attached to its deep surface. The following features of the fibrous pericardium are noteworthy:

1. The apex is blunt and lies at the level of the sternal angle. It is fused with the roots of the great vessels and with the pretracheal fascia.
2. The base is broad and inseparably blended with the central tendon of the diaphragm. In lower mammals or quadrupeds it is separated from the diaphragm by the infracardiac bursa.
3. Anteriorly, it is connected to the upper and lower ends of body of the sternum by weak superior and inferior sternopericardial ligaments (Fig. 18.3).
4. Posteriorly, it is related to the principal bronchi, the oesophagus with the nerve plexus around it and the descending thoracic aorta.

1. On each side it is related to the mediastinal pleura, the mediastinal surface of the lung, the phrenic nerve, and the pericardiophrenic vessels.
2. It protects the heart against sudden overfilling.

**SEROUS PERICARDIUM**

Serous pericardium is thin, double-layered serous membrane lined by mesothelium. The outer layer of parietal pericardium is fused with the fibrous pericardium. The inner layer or the visceral pericardium, or epicardium is fused to the heart, except along the cardiac grooves, where it is separated from the heart by blood vessels. The two layers are continuous with each other at the roots of the great vessels, i.e. ascending aorta, pulmonary trunk, two venae cavae, and four pulmonary veins.

The pericardial cavity is a potential space between the parietal pericardium and the visceral pericardium. It contains only a thin film of serous fluid which lubricates the apposed surfaces and allows the heart to move smoothly.

**Contents of the Pericardium**

(i) Heart with cardiac vessels and nerves, (ii) ascending aorta, (iii) pulmonary trunk, (iv) lower half of the superior vena cava, (v) terminal part of the inferior vena cava, and (vi) the terminal parts of the pulmonary veins.
Sinuses of Pericardium

The epicardium at the roots of the great vessels is arranged in form of two tubes. The arterial tube encloses the ascending aorta and the pulmonary trunk at the arterial end of the heart tube, and the venous tube encloses the venae cavae and pulmonary veins at the venous end of the heart tube. The passage between the two tubes is known as the transverse sinus of pericardium. During development, to begin with the veins of the heart are crowded together. As the heart increases in size and these veins separate out, a pericardial reflection surrounds all of them and forms the oblique pericardial sinus. This cul-de-sac is posterior to the left atrium (Fig. 18.4).

The transverse sinus is a horizontal gap between fee arterial and venous ends of the heart tube. It is bounded anteriorly by the ascending aorta and pulmonary trunk, and posteriorly by the superior vena cava and inferiorly by the left atrium: on each side it opens into the general pericardial cavity) (Fig. 18.5). The oblique sinus is a narrow gap behind the heart. It is bounded anteriorly by the left atrium, and posteriorly by the parietal pericardium. On the right and left sides it is bounded by reflections of pericardium as shown in Fig. 18.5. Below, and to the left it opens into the rest of the pericardial cavity. The oblique sinus permits pulsations of the left atrium to take place freely (Figs 18.4, 18.5).

Arterial Supply

The fibrous and parietal pericardia are supplied by branches from: (i) internal thoracic, and (ii) muscu-
Nerve Supply
The fibrous and parietal pericardia are supplied by the phrenic nerve. They are sensitive to pain. The epicardium is supplied by autonomic nerves of the heart, and is not sensitive to pain. Pain of pericarditis originates in the parietal pericardium alone. On the other hand cardiac pain or angina originates in the cardiac muscle or in the vessels of the heart.

CLINICAL ANATOMY
Collection of fluid in the pericardial cavity is referred to as pericardial effusion. Pericardial effusion can be drained by puncturing the left fifth or sixth intercostal space just lateral to the sternum, or in the angle between the xiphoid process and left costal margin, with the needle directed upwards, backwards and to the left.

THE HEART
Introduction
The heart is a conical hollow muscular organ situated in the middle mediastinum. It is enclosed within the pericardium. It pumps blood to various parts of the body to meet their nutritive requirements. The Greek name for the heart is cardia from which we have the adjective cardia. The Latin name for the heart is cor from which we have the adjective coronary.
The heart is placed obliquely behind the body of the sternum and adjoining parts of the costal cartilages, so that one-third of it lies to the right and two-thirds to the left of the median plane. The direction of blood flow, from atria to the ventricles is downwards forwards and to the left. The heart measures about 12 x 9 cm and weighs about 300 g in males and 250 g in females.

~ EXTERNAL FEATURES ~

The human heart has four chambers. These are the right and left atria and the right and left ventricles. The atria lie above and behind the ventricles. On the surface of the heart they are separated from the ventricles by an atrioventricular groove. The atria are separated from each other by an interatrial groove. The ventricles are separated from each other by an interventricular groove, which is subdivided into anterior and posterior parts (Fig. 18.6).

The heart has an apex directed downwards forwards and to the left, a base (or posterior surface) directed backwards; and anterior, inferior and left surfaces. The surfaces are demarcated by upper, lower, right and left borders.

Grooves or Sulci

The atria are separated from the ventricles by a circular atrioventricular or coronary sulcus. It is overlapped anteriorly by the ascending aorta and the pulmonary trunk. The interatrial groove is faintly visible posteriorly. While anteriorly it is hidden by the aorta and pulmonary trunk. The anterior interventricular groove is nearer to the left margin of the heart. It runs downwards and to the left. The lower end of the groove separates the apex from the rest of the inferior border of the heart. The posterior interventricular groove is situated on the diaphragmatic or inferior surface of the heart. It is nearer to the right margin of this surface. The two interventricular grooves meet at the inferior border near the apex (Fig. 18.6).

Apex of the Heart

Apex of the heart is formed entirely by the left ventricle. It is directed downwards forwards and to the left and is overlapped by the anterior border of the left lung. It is situated in the left fifth intercostal space 9 cm lateral to the midsternal line just medial to the midclavicular line. In the living subject, pulsations may be seen and felt over this region.
Base of the Heart

The base of the heart is also called its posterior surface. It is formed mainly by the left atrium and by a small part of the right atrium. In relation to the base we see the openings of four pulmonary veins which open into the left atrium; and of the superior and inferior venae cavae which open into the right atrium. It is related to thoracic five to thoracic eight vertebrae in the lying posture, and descends by one vertebra in the erect posture. It is separated from the vertebral column by the pericardium, the right pulmonary veins, the oesophagus and the aorta (Fig. 18.7).

Note that clinicians often refer to the upper border of the heart as the base.

Borders of the Heart

The upper border is slightly oblique, and is formed by the two atria, chiefly the left atrium. The right border is more or less vertical and is formed by the right atrium. The inferior border is nearly horizontal and is formed mainly by the right ventricle. A small part of it near the apex is formed by left ventricle. The left border is oblique and curved. It is formed mainly by the left ventricle, and partly by the left auricle. It separates the anterior and left surfaces of the heart (Fig. 18.6).

Surfaces of the Heart

The anterior or sternocostal surface is formed mainly by the right atrium and right ventricle: and partly by the left ventricle and left auricle. The left atrium is not seen on the anterior surface as it is covered by
the aorta and pulmonary trunk. Most of the sternocostal surface is covered by the lungs, but a part of it that lies behind the cardiac notch of the left lung is uncovered. The uncovered area is dull on percussion. Clinically it is referred to as the area of superficial cardiac dullness.

The inferior or diaphragmatic surface rests on the central tendon of the diaphragm. It is formed in its left two-thirds by the left ventricle, and in its right one-third by the right ventricle. It is traversed by the posterior interventricular groove, and is directed downwards and slightly backwards: The left surface is formed mostly by the left ventricle, and at the upper end by the left auricle. In its upper part, the surface is crossed by the coronary sulcus. It is related to the left phrenic nerve, the left pericardiophrenic vessels, and the pericardium.

Surface Marking of the Borders of the Heart

The upper border is marked by a straight line joining: (i) a point at the lower border of the second left costal cartilage about 1.3 cm from the sternal margin to, (ii) a point at the upper border of the third right costal cartilage 0.8 cm from the sternal margin (Fig. 18.8)

The lower border is marked by a straight line joining: (i) a point at the lower border of the sixth right costal cartilage 2 cm from the sternal margin to, (ii) a point at the apex of the heart in the left fifth intercostal space 9 cm from the midsternal line.

The right border is marked by a line, slightly convex to the right, joining the right ends of the upper and lower borders. The maximum convexity is about 3.8 cm from the median plane in the fourth space.
The left border is marked by a line, fairly convex to the left, joining the left ends of the upper and lower borders.

The area of the chest wall overlying the heart is called the precardium.

**Fibrous Skeleton**

The fibrous rings surrounding the atrioventricular and arterial orifices, along with some adjoining masses of fibrous tissue, constitute the fibrous skeleton of the heart. It provides attachment to the cardiac muscle and keeps the cardiac valve competent (Fig. 18.9).

The atrioventricular fibrous rings are in the form of the figure of 8. The atria, the ventricles and the membranous part of the interventricular septum are attached to them. There is no muscular continuity between the atria and ventricles across the rings except for the atrioventricular bundle or bundle of His.

There is large mass of fibrous tissue between the atrioventricular rings behind and the aortic ring in front. It is known as the trigonum fibrosum dextrum. In some mammals like sheep, a small bone the os cordis is present in this mass of fibrous tissue.

Another smaller mass of fibrous tissue is present between the aortic and mitral rings. It is known as the trigonum fibrosum sinistrum. The tendon of the infundibulum binds the posterior surface of the infundibulum to the aortic ring.

**Musculature of the Heart**

Cardiac muscle fibres form long loops which are attached to the fibrous skeleton. Upon contraction the muscular loops the blood from the cardiac chambers is wrung out like water from a wet cloth. The atrial fibres are arranged in a superficial transverse layer and a deep anteroposterior (vertical) layer.

The ventricular fibres are arranged in superficial, middle and deep layers. The superficial fibres arise from skeleton of the heart to undergo a spiral course. First these pass across the inferior surface, wind round the lower border and then across the sternocostal surface to reach the apex of heart: where these fibres form a vortex and continue with the deep layer.

The middle layer of fibres of heart are thickest. The fibres of the left side arise from left atrioventricular ring, pass in front of the left ventricle and are inserted into tendon of infundibulum and around the aortic and pulmonary rings.

The fibres of the right side also arise from the left atrioventricular ring, pass in front of the left ventricle and are inserted into tendon of infundibulum and around the aortic and pulmonary rings.

The fibres of the right side also arise from the left atrioventricular ring and soon divide at the posterior interventricular sulcus into circular and longitudinal branches. The circular fibres pass around the right ventricle and unite with the septal fibres of the anterior interventricular groove. The longitudinal fibres pass down in the interventricular septum.

The deep layer of fibres pass at right angles to the superficial layer to get continuous with the papillary muscles of both the ventricles. Lastly they get continuous with the chordae tendinae and are attached back to the skeleton of the heart.

**Histology of Cardiac Muscle**

Cardiac muscle is specialised type of muscle found in the myocardium. The cell is a short cylinder, with striations and a single central nucleus surrounded by a light perinuclear space. These cells branch, and at regular intervals, the cytoplasm reveals a transverse dark line called the 'intercalated disc'. It has partial properties both of the skeletal and the smooth muscles of fibres.

**THE RIGHT ATRIUM**

The right atrium is the right upper chamber of the heart. It receives venous blood from the whole body, pumps it to the right ventricle through the right atrioventricular or tricuspid opening. It forms the right border, part of the upper border, the sternocostal surface and the base of the heart.
Cut along the upper edge of the right auricle by an incision from the anterior end of the superior vena caval opening to the left side. Similarly cut along its lower edge by an incision extending from the anterior end of the inferior vena caval opening to the left side. Incise the anterior wall of the right auricle near its left margin and reflect the flap to the right (Fig. 18.10). On its internal surface, see the vertical crista terminalis and horizontal pectinate muscles. The fossa ovalis is on the interatrial septum and the opening of the coronary sinus is to the left of the inferior vena caval opening. Define the three cusps of tricuspid valve.

External Features

1. The chamber is elongated vertically, receiving the superior vena cava at the upper end and the inferior vena cava at the lower end (Fig. 18.6).
2. The upper end is prolonged to the left to form the right auricle. The auricle covers the root of the ascending aorta and partly overlaps the infundibulum of the right ventricle. Its margins are notched and the interior is sponge-like, which prevents free flow of blood.
3. Along the right border of the atrium there is a shallow vertical groove which passes from the superior vena cava above to the inferior vena cava below. This groove is called the sulcus terminalis. It is produced by an internal muscular ridge called the crista terminalis (Fig. 18.10). The upper part of the sulcus contains the sinoatrial or SA node which acts as the pacemaker of the heart.

4. The right atrioventricular groove separates the right atrium from the right ventricle. It is more or less vertical and lodges the right coronary artery and the small cardiac vein.

Tributaries or Inlets of the Right Atrium
(i) Superior vena cava, (ii) inferior vena cava, (iii) coronary sinus, (iv) anterior cardiac veins, (v) venae cordis minimi (Thebesian veins), (vi) and sometimes the right marginal vein.

Right Atrioventricular Orifice
Blood passes out of the right atrium through the right atrioventricular or tricuspid orifice and goes to the right ventricle. The tricuspid orifice is guarded by the tricuspid valve which maintains unidirectional flow of blood (Fig. 18.11).
Internal Features

The interior of the right atrium can be broadly divided into the following three parts.

The Smooth Posterior Part or Sinus Venarum

1. Developmentally it is derived from the right horn of the sinus venosus.

2. Most of the tributaries except the anterior cardiac veins open into it. (i) The *superior vena cava* opens at the upper end. (ii) The *inferior vena cava* opens at the lower end. The opening is guarded by a rudimentary valve of the inferior vena cava or Eustachian valve. During embryonic life the valve guides the inferior vena caval blood to the left atrium through the foramen ovale, (iii) The *coronary sinus* opens between the opening of the inferior vena cava and the right atrioventricular orifice. The opening is guarded by the *valve of the coronary sinus*, (iv) The venae cordis minimae are numerous small veins present in the walls of all the four chambers. They open into the right atrium through small foramina.

3. The *intervenous tubercle* of Lower is a very small projection, scarcely visible, on the posterior wall of the atrium just below the opening of the superior vena cava. During embryonic life it directs the superior caval blood to the right ventricle.

THE RIGHT VENTRICLE

The right ventricle is a triangular chamber which receives blood from the right atrium and pumps it to the lungs through the pulmonary trunk and pulmonary arteries. It forms the inferior border and a large part of the sternocostal surface of the heart (Fig. 18.6).

DISSECTION

Incise along the ventricular aspect of right AV groove, till you reach the inferior border. Continue to incise along the inferior border till the inferior end of anterior interventricular groove. Next cut along the infundibulum. Now the anterior wall of right ventricle is reflected to the left to study its interior.

Features

1. Externally, the right ventricle has two surfaces: *anterior* or *sternocostal* and *inferior diaphragmatic*.

2. The interior has two parts, (i) The *inflowing part* is rough due to the presence of muscular ridges called *trabeculae carneae*. It develops from the proximal part of bulbus cordis of the heart tube, (ii) The *outflowing part or infundibulum* is smooth and forms the upper conical part of the right ventricle which gives rise to the pulmonary trunk. It develops from the mid portion of the bulbus cordis.

The two parts are separated by a muscular ridge called the *supraventricular crest* or infundi-buloventricular crest situated between the tricuspid and pulmonary orifices.

1. The interior shows two orifices: (i) the right atrioventricular or tricuspid orifice, guarded by the tricuspid valve, and (ii) the pulmonary orifice guarded by the pulmonary valve (Fig. 18.11).

2. The interior of the inflowing part shows *trabeculae carneae* or muscular ridges of three types: (i) *ridges* or fixed elevations, (ii) *bridges*, (iii) *pillars* or papillary muscles with one end attached to the ventricular wall, and the other end connected to the cusps of the tricuspid valve by chordae tendineae. There are three papillary muscles in the right ventricle, anterior, posterior and septal. The anterior muscle is the largest (Fig. 18.12). The posterior or inferior muscle is small and irregular. The septal muscle is divided into a number of little nipples.
1. Developmentally it is derived from the primitive atrial chamber.

2. It presents a series of transverse muscular ridges called musculi pectinati. They arise from the crista terminalis and run forwards and downwards towards the atrioventricular orifice, giving the appearance of the teeth of a comb. In the auricle, the muscles are interconnected to form a reticular network.

**Interatrial Septum**

1. Developmentally it is derived from the septum primum and septum secundum.

2. It presents the fossa ovalis, a shallow saucer-shaped depression, in the lower part. The fossa represents the site of the embryonic septum primum.

3. The annulus ovalis or limbus fossa ovalis is the prominent margin of the fossa ovalis. It represents the lower free edge of the septum secundum. It is distinct above and at the sides of the fossa ovalis, but is deficient inferiorly. Its anterior edge is continuous with the left end of the valve of the inferior vena cava.

4. The remains of the foramen ovale are occasionally present. This is a small slit-like valvular opening.
Each papillary muscle is attached by chordae to the contiguous sides of two cusps (Fig. 18.13)

1. The septomarginal trabecula or moderator band is a muscular ridge extending from the ventricular septum to the base of the anterior papillary muscle. It contains the right branch of the AV bundle (Figs 18.12, 18.14).
2. The cavity of the right ventricle is crescentic in section because of the forward bulge of the interventricular septum (Fig. 18.11).
3. The wall of the right ventricle is thinner than that of the left ventricle in a ratio of 1:3.

**Interventricular Septum**

The septum is placed obliquely. Its one surface faces forwards and to the right and the other faces backwards and to the left. The upper part of the septum is thin and membranous and separates not only the two ventricles but also the right atrium and left ventricle. The lower part is thick muscular separates the two ventricles. Its position is indic
THE LEFT ATRIUM

The left atrium is a quadrangular chamber situated posteriorly. Its appendage, the left auricle projects anteriorly to overlap the infundibulum of the right ventricle. The left atrium forms the left two-thirds of the base of the heart, the greater part of the upper border, parts of the sternocostal and left surfaces and of the left border. It receives oxygenated blood from the lungs through four pulmonary veins, and pumps it to the left ventricle through the left atrioventricular or bicuspid or mitral orifice which is guarded by the valve of the same name.

Features

1. The posterior surface of the atrium forms the anterior wall of the oblique sinus of pericardium (Fig. 18.5).
2. The anterior wall of the atrium is formed by the interatrial septum.
3. Two pulmonary veins open into the atrium on each side of the posterior wall (Fig. 18.7).
4. The greater part of the interior of the atrium is smooth walled. It is derived embryologically from the absorbed pulmonary veins which open into it. Musculi pectinati are present only in the auricle where they form a reticulum. This part develops from the original primitive atrial chamber of the heart tube. The septal wall shows the fossa lunata corresponding to the fossa ovalis of the right atrium. In addition to the four pulmonary veins, the tributaries of the atrium include a few venae cordis minimi.
The left ventricle receives oxygenated blood from the left atrium and pumps it into the aorta. It forms the apex of the heart, a part of the sternocostal surface, most of the left border and left surface, and the left two-thirds of the diaphragmatic surface (Figs 18.6, 18.13).

Features

1. Externally, the left ventricle has three surfaces: anterior or sternocostal, inferior or diaphragmatic, and left.
2. The interior is divisible into two parts: (i) the lower rough part with or trabeculae carneae develops from the primitive ventricle of the heart tube, (ii) the upper smooth part or aortic vestibule gives origin to the ascending aorta: it develops from the mid portion of the bulbus cordis. The vestibule lies between the membranous part of the interventricular septum and the anterior or aortic cusp of the mitral valve.
3. The interior of the ventricle shows two orifices: (i) The left atrioventricular or bicuspid or mitral orifice, guarded by the bicuspid or mitral valve, and (ii) the aortic orifice, guarded by the aortic valve (Fig. 18.15).
4. There are two well-developed papillary muscles, anterior and posterior. Chordae tendinae from both

The valves of the heart maintain unidirectional flow of the blood and prevent its regurgitation in the opposite direction. There are two pairs of valves in the heart, a pair of atrioventricular valves and a pair of semilunar valves. The right atrioventricular valve is known as the tricuspid valve because it has three cusps. The left atrioventricular valve is known as the bicuspid valve because it has two cusps. It is also called the mitral valve. The semilunar valves include the aortic and pulmonary valves, each having three semilunar cusps. The cusps are folds of endocardium, strengthened by an intervening layer of fibrous tissue (Fig. 18.9).

Atrioventricular Valves

1. Both valves are made up of the following components: (i) a fibrous ring to which the cusps are attached (Fig. 18.13). (ii) The cusps are flat and project into the ventricular cavity. Each cusp has an attached and a free margin, and an atrial and a ventricular surface. The atrial surface is smooth (Fig. 18.16). The free margins and ventricular surfaces are rough and irregular due to the attachment of chordae tendinae. The valves are closed during ventricular systole by apposition of the atrial surfaces.
near the serrated margins, (iii) The chordae tendinae connect the free margins and ventricular surfaces of the cusps to the apices of the papillary muscles. They prevent eversion of the free margins and limit the amount of ballooning of the cusps towards the cavity of the atrium, (iv) The atrioventricular valves are kept competent by active contraction of the papillary muscles, which pull on the chordae tendinae during ventricular systole. Each papillary muscle is connected to the contiguous halves of two cusps (Figs 18.11, 18.13).

1. Blood vessels are present only in the fibrous ring and in the basal one-third of the cusps. Nutrition to the central two-thirds of the cusps is derived directly from the blood in the cavity of the heart.

2. The tricuspid valve has three cusps and can admit the tips of three fingers. The three cusps, the anterior, posterior or inferior, and septal lie against the three walls of the ventricle. Of the three papillary muscles, the anterior is the largest, the inferior is smaller and irregular, and the septal is represented by a number of small muscular elevations.

3. The mitral or bicuspid valve has two cusps, a large anterior or aortic cusp, and a small posterior cusp. It admits the tips of two fingers. The anterior cusp lies between the mitral and aortic orifices. The mitral cusps are smaller and thicker than those of the tricuspid valve.

Semilunar Valves

1. The aortic and pulmonary valves are called semilunar valves because their cusps are semilunar in shape. Both valves are similar to each other (Fig. 18.17).

1. Each valve has three cusps which are attached directly to the vessel wall, there being no fibrous ring. The cusps form small pockets with their mouths directed away from the ventricular cavity. The free margin of each cusp contains a central fibrous nodule from each side of which a thin smooth margin the lunule extends up to the base of the cusp. These valves are closed during ventricular diastole when each cusp bulges towards the ventricular cavity (Fig. 18.17).

2. Opposite the cusps the vessel walls are slightly dilated to form the aortic and pulmonary sinuses. The coronary arteries arise from the anterior and the left posterior aortic sinuses (Fig. 18.19).

Surface Marking of the Cardiac Valves and the Auscultatory Areas

Sound produced by closure of the valves of the heart can be heard using a stethoscope. The sound arising in relation to a particular valve are best heard not directly over the valve, but at areas situated some distance away from the valve in the direction of blood flow through it. These are called auscultatory areas. The position of the valves in relation to the surface of the body, and of the auscultatory areas is given in Table 18.1 and Fig. 18.18.

Conducting System

The conducting system is made up of myocardium that is specialized for initiation and conduction of the cardiac impulse. Its fibres are finer than other myocardial fibres, and are completely cross-striated. The conducting system has the following parts:

1. Sinuatrial Node or SA node. It is known as the 'pacemaker' of the heart. It generates an impulse at the rate of about 70/ min and initiates the heart beat. It is horseshoe-shaped and is situated at the

2. **Atrioventricular node** or **AV node.** It is smaller than the SA node and is situated in the lowe and dorsal part of the atrial septum just above the opening of the coronary sinus. It is capable of generating impulses at a rate of about 60/ min.

1. **Atrioventricular bundle** or **AV bundle of His.** It is the only muscular connection between the atrial and ventricular musculatures. It begins as the atrioventricular (AV) node crosses a ring and descends along the posteroinferior borde of the membranous part of the ventricular septum. At the upper border of the muscular part of the septum it divides into right and left branches.

2. **The right branch** of the AV bundle passe down the right side of the interventricular septum, large part enters the moderator band to reach the anterior wall of the right ventricle where it divide into Purkinje fibres.

3. **The left branch** of the AV bundle descends the left side of the interventricular septum and is distributed to the left ventricle after dividing into Purkinje fibres.

4. **The Purkinje fibres** form a subendocardial plexus. They are large pale fibres striated only a their margins. They usually possess double nucle:

Defects of or damage to this system results in cardiac arrhythmias, i.e. defects in the normal rhythm of contraction. Except for a part of the left branch c the AV bundle supplied by the left coronary arter the whole of the conducting system is usually supplied by the right coronary artery. Vascular lesions c the heart can cause a variety of arrhythmias.

---

**CLINICAL ANATOMY**

1. The first heart sound is produced by closure of the atroventricular valves. The second heart sound is produced by closure of the semilunar valves.

2. Narrowing of the valve orifice due to fusion of the cusps is known as 'stenosis', viz. mitral stenosis, aortic stenosis, etc.

3. Dilatation of the valve orifice, or stiffening of the cusps causes imperfect closure of the valve leading to back-flow of blood. This is known as incompetence or aortic regurgitation, e.g. aortic incompetence or aortic regurgitation.

---

**ARTERIES SUPPLYING THE HEART**

The heart is supplied by two coronary arteries arising from the ascending aorta. Both arteries run in the coronary sulcus.
Carfully remove the fat from the coronary sulcus. Identify the right coronary artery in the depth of the right part of the atrioventricular sulcus. Trace the right coronary artery superiorly to its origin from the right aortic sinus and inferiorly till it turns on to the posterior surface of the heart to lie in its atrioventricular sulcus. It gives off the posterior interventricular branch which is seen in posterior interventricular groove. The right coronary ends by anastomosing with the circumflex branch of left coronary artery or by dipping itself deep in the myocardium there.

Right Coronary Artery
Right coronary artery is smaller than the left coronary artery. It arises from the anterior aortic sinus (Fig. 18.19).

Course
1. It first passes forwards and to the right to emerge on the surface of the heart between the root of the pulmonary trunk and the right auricle.
2. It then runs downwards in the right anterior coronary sulcus to the junction of the right and inferior borders of the heart.
3. It winds round the inferior border to reach the diaphragmatic surface of the heart. Here it runs backwards and to the left in the right posterior coronary sulcus to reach the posterior interventricular groove.
4. It terminates by anastomosing with the left coronary artery.

Branches
(A) Large branches: (1) Marginal, and (2) posterior interventricular.
(B) Small branches: (1) Nodal in 60% cases, (2) right atrial, (3) infundibular, and (4) terminal.

Area of Distribution
1. Right atrium
2. Ventricles
   (i) Greater part of the right ventricle, except the area adjoining the anterior interventricular groove.
   (ii) A small part of the left ventricle adjoining the posterior interventricular groove.
3. Posterior part of the interventricular septum.
4. Whole of the conducting system of the heart except a part of the left branch of the AV bundle. The SA node is supplied by the left coronary artery in about 40% of cases.

Left Coronary Artery
Left coronary artery is larger than the right coronary artery. It arises from the left posterior aortic sinus.
surface of the heart. Expose the anterior interventricular branch of the left coronary artery and the great cardiac vein by carefully removing the fat from the anterior interventricular sulcus. Note the branches of the artery to both ventricles and to the interventricular septum which lies deep to it. Trace the artery inferiorly to the diaphragmatic surface and superiorly to the left of the pulmonary trunk. Trace the circumflex branch of left coronary artery on the left border of heart into the posterior part of the sulcus, where it may end by anastomosing with the right coronary artery or by dipping into the myocardium.

**Course**

1. The artery first runs forwards and to the left and emerges between the pulmonary trunk and the left auricle. Here it gives the anterior interventricular branch which runs downwards in the groove of the same name. The further continuation of the left coronary artery is called the circumflex artery (Fig. 18.20).
2. After giving off the anterior interventricular branch the artery runs to the left in the left anterior coronary sulcus.
3. It winds round the left border of the heart and continues in the left posterior coronary sulcus. Near the posterior interventricular groove it terminates by anastomosing with the right coronary artery.
**Branches**

A. **Large branches**

1. Anterior interventricular, to the diaphragmatic surface of the left ventricle, including a large diagonal branch.

B. **Small branches**

1. Left atrial, (2) pulmonary, (3) terminal.

**Area of Distribution**

1. Left atrium
2. Ventricle
   1. Greater part of the left ventricle, except the area adjoining the posterior interventricular groove.
   2. A small part of the right ventricle adjoining the anterior interventricular groove.
3. Anterior part of the interventricular septum (Fig 18.21).
4. A part of the left branch of the AV bundled

**Cardiac Dominance**

In about 10% of hearts, the right coronary is rather small and is not able to give the posterior interventricular branch. In these cases the circumflex artery, the continuation of left coronary provides the posterior interventricular branch as well as to the AV node. Such cases are called as left dominant.

Mostly the right coronary gives posterior interventricular artery. Such hearts are right dominant. Thus *the* artery giving the posterior interventricular branch is the dominant artery.
Collateral Circulation

**Cardiac anastomosis:** The two coronary arteries anastomose with each other in myocardium.

**Extracardiac anastomoses:** The coronary arteries anastomose with the: (i) vasa vasorum of the aorta: (ii) vasa vasorum of the pulmonary arteries: (iii) the internal thoracic arteries, (iv) the bronchial arteries, and (v) the phrenic arteries. The last three anastomose through the pericardium. These channels may open up in emergencies when both coronary arteries are obstructed. Retrograde flow of blood in the veins may irrigate the myocardium.

These anastomoses are of little practical value. They are not able to provide an alternative source of blood in case of blockage of a branch of a coronary. Blockage of arteries or coronary thrombosis usually leads to death of myocardium. The condition is called myocardial infarction.

CLINICAL ANATOMY

1. Thrombosis of a coronary artery is a common cause of sudden death in persons past middle age. This is due to myocardial infarction and ventricular fibrillation.
2. Incomplete obstruction, usually due to spasm of the coronary artery causes angina pectoris, which is associated with agonising pain in the precordial region and down the medial side of the left arm and forearm.
3. Coronary angiography determines the site(s) of narrowing or occlusion of the coronary arteries or their branches.
1. Angioplasty helps in removal of small blockage. It is done using small stent or small inflated balloon.
2. If there are large segments or multiple sites of blockage, coronary bypass is done using either great saphenous vein or internal thoracic artery as graft(s).

THE VEINS OF THE HEART

These are the great cardiac vein, the middle cardiac vein, the right marginal vein, the posterior vein of the left ventricle, the oblique vein of the left atrium, the right marginal vein, the anterior cardiac veins, and the venae cordis minimi (Fig. 18.22). All veins except the last two drain into the coronary sinus which opens into the right atrium. The anterior cardiac veins and the venae cordis minimae open directly into the right atrium.

A. Coronary sinus: The coronary sinus is the largest vein of the heart. It is situated in the left posterior coronary sulcus. It is about 3 cm long. It ends by opening into the posterior wall of the right atrium. It receives the following tributaries.

1. The great cardiac vein accompanies first the anterior interventricular artery and then the left coronary artery to enter the left end of the coronary sinus (Fig. 18.22).
2. The middle cardiac vein accompanies the posterior interventricular artery, and joins the middle part of the coronary sinus.
3. The **small cardiac vein** accompanies the right coronary artery in the right posterior coronary sulcus and joins the right end of the coronary sinus. The right marginal vein may drain into the small cardiac vein.

4. The **posterior vein of the left ventricle** runs on the diaphragmatic surface of the left ventricle and ends in the middle of the coronary sinus.

5. The **oblique vein of the left atrium of Marshallis** a small vein running on the posterior surface of the left atrium. It terminates in the left end of the coronary sinus. It develops from the left common cardinal vein or duct of Cuvier which may sometimes form a large left superior vena cava.

6. The **right marginal vein** accompanies the marginal branch of the right coronary artery. It may either drain into the small cardiac vein, or may open directly into the right atrium.

**B. Anterior cardiac veins:** The **anterior cardiac veins** are three or four small veins which run parallel to one another on the anterior wall of the right ventricle and usually open directly into the right atrium through its anterior wall.

**C. Venae cordis minimi:** The **venae cordis minimi or Thesbian veins or smallest cardiac veins** are numerous small veins present in all four chambers of the heart which open directly into the cavity. These are more numerous on the right side of the heart than on the left. This may be one reason why left sided infarcts are more common.

---

### LYMPHATICS OF THE HEART

Lymphatics of the heart accompany the coronary arteries and form two trunks. The right trunk ends in the brachiocephalic nodes, and the left trunk ends in the tracheobronchial lymph nodes at the bifurcation of the trachea.

### NERVE SUPPLY OF THE HEART

Parasympathetic nerves reach the heart via the vagus. These are cardioinhibitory; on stimulation they slow down the heart rate. Sympathetic nerves are derived from the upper two to five thoracic segments of the spinal cord. These are cardio-, acceleratory, and on stimulation they increase the heart rate, and also dilate the coronary arteries. Both parasympathetic and sympathetic nerves form the superficial and deep cardiac plexuses, the branches of which run along the coronary arteries to reach the myocardium (Figs 14.13).

The **superficial cardiac plexus** is situated below the arch of the aorta in front of the right pulmonary artery. It is formed by: (i) the superior cervical cardiac branch of the left sympathetic chain; and (ii) the inferior cervical cardiac branch of the left vagus nerve. It gives branches to the deep cardiac plexus, the right coronary artery, and to the left anterior pulmonary plexus.

The **deep cardiac plexus** is situated in front of the bifurcation of the trachea, and behind the arch of the aorta. It is formed by all the cardiac branches derived from all the cervical and upper thoracic ganglia of the sympathetic chain, and the cardiac branches of the vagus and recurrent laryngeal nerves, except those which form the superficial plexus. The right and left halves of the plexus distribute branches to the corresponding coronary and pulmonary plexuses. Separate branches are given to the atria.

---

### DEVELOPMENT OF HEART

The central part of intraembryonic coelom forms the pericardial cavity. The cavity has a parietal wall lined by mesothelium derived from somatic mesoderm and a visceral wall derived from splanchnic mesoderm. The two together form the serous pericardium. The pleuropericardial membrane which partitions off the pleural and pericardial cavities form the fibrous pericardium of the heart.

The heart tube with its venous and arterial ends gets invaginated into the pericardial cavity. The site of invagination is the dorsal mesocardium. Soon the dorsal mesocardium gets absorbed, resulting in the formation of transverse sinus of the pericardium. Reflection of pericardium along the veins entering the heart gives rise to oblique sinus of the pericardium (Figs 18.4, 18.5).

The splanchnic mesenchymal cells in the cardiogenic area ventral to developing pericardial cavity form two endocardial heart tubes which soon fuse to form a single tube. The heart tube shows two ends — arterial and venous and shows alternate constrictions and dilatations. The dilatations are bulbus cordis, the ventricle, common atria and sinus veno-sus. The straight tube forms a loop due to paucity of space, so that cranial portion lies ventrocaudally and caudal atrial portion shifts dorsocranially.

Bulbus cordis gets divided into a distal cranial part the truncus arteriosus, a middle part the conus cordis and a proximal dilated part which forms the trabeculated part of the right ventricle (RV). The conus cordis part of bulbus cordis forms part of ventricles, e.g. infundibulum of RVand the vestibule of left ventricle (LV). The right and left bulbar ridges with the endocardial cushion form the membranous part of interventricular septum.
Simultaneously the common atrium gets divided into right and left atria by the interatrial septum. From the roof of the common atrial chamber first septum to arise is septum primum (SP). Ostium primum is the foramen between the lower end of septum and the endocardial cushion. Soon this septum joins the cushion and ostium primum gets obliterated. SP degenerates in upper part and is called ostium secundum. A crescentic septum, the septum secundum appears on the right side of SP. Now the passage, between the two atria is valvular and is called foramen ovale. After birth the two septae fuse to form interatrial septum.

The sinus venosus modifies and can be divided into three parts: right and left horns and body. The right horn gets incorporated into the right atrium while the left horn and body give rise to the coronary sinus.

Developmental Components of Heart

1. Right atrium (Fig. 18.10)
   a. Rough anterior part — atrial chamber proper.
   b. Smooth posterior part
      i. absorption of right horn of sinus venosus ii.
         interatrial septum Dermarcating part — crista terminals.

2. Left atrium (Fig. 18.7)
   a. Rough part — atrial chamber proper
   b. Smooth part —
      i. absorption of pulmonary veins ii.
         interatrial septum
1. One umbilical vein
2. Ductus venosus
3. Foramen ovale
4. Ductus arteriosus

5. Two umbilical arteries

At the time of birth and the start of breathing, these structures (1-5) retrogress and gradually the adult form of circulation takes over.
1. The area of the chest wall overlying the heart is called the **precardium**.
2. Rapid pulse or increased heart rate is called **tachycardia**.
3. Slow pulse or decreased heart rate is called **bradycardia**.
4. Irregular pulse or irregular heart rate is called **arrhythmia**.
5. Consciousness of one's heart beat is called **palpitation**.
6. Inflammation of the heart can involve more than one layer of the heart. Inflammation of the pericardium is called **pericarditis**; of the myocardium is **myocarditis**; and of the endocardium is **endocarditis**.
7. Normally the diastolic pressure in ventricles is zero. A positive diastolic pressure in the ventricle is evidence of its failure. Any one of the four chambers of the heart can fail separately, but ultimately the rising back pressure causes right sided failure (congestive cardiac failure or CCF) which is associated with increased venous pressure, oedema on feet, and breathlessness on exertion. Heart failure (right sided) due to lung disease is known as **cor pulmonale**.
8. Normally the cardiac apex or apex beat is on the left side. In the condition called dextrocardia, the apex is on the right side. Dextrocardia may be part of a condition called **situs inversus** in which all thoracic and abdominal viscera are a mirror image of normal.
9. Cardiac pain is an ischaemic pain caused by incomplete obstruction of a coronary artery.

**Axons of pain fibres conveyed by the sensory sympathetic cardiac nerves reach thoracic one to thoracic five segments of spinal cord mostly through the dorsal root ganglia of the left side. Since these dorsal root ganglia also receive sensory impulses from the medial side of arm, forearm and upper part of front of chest, the pain gets referred to these areas as depicted in Fig. 18.24.**

Though the pain is usually referred to the left side, it may even be referred to right arm, jaw, epigastrium or back?)

![Fig. 18.24: Usual distribution and referral of pain in angina pectoris.](image)
S
uperior vena cava brings deoxygenated blood from the head and neck, upper limbs and thorax to the heart. Aorta and pulmonary trunk are the only two exit channels from the heart, developing from a single truncus arteriosus. The two are intimately related to each other.

**SUPERIOR VENA CAVA**

Superior vena cava is a large venous channel which collects blood from the upper half of the body and drains it into the right atrium. It is formed by the union of the right and left brachiocephalic or innominate veins behind the lower border of the first right costal cartilage close to the sternum. Each brachiocephalic vein is formed behind the corresponding sternoclavicular joint by the union of the internal jugular and subclavian veins (Fig. 19.1).

The superior vena cava is about 7 cm long. It begins behind the lower border of the sternal end of the first right costal cartilage, pierces the pericardium opposite the second right costal cartilage, and terminates by opening into the upper part of the right atrium behind the third right costal cartilage (Fig. 19.2). It has no valves.

**Surface Marking**

7. *Superior Vena Cava*

It is marked by two parallel lines 2 cm apart, drawn from the lower border of the right first costal cartilage to the upper border of the third right costal cartilage, overlapping the right margin of the sternum (Fig. 19.1).

2. *Right Brachiocephalic Vein*

It is marked by two parallel lines 1.5 cm apart, drawn from the medial end of the right clavicle to the lower
border of the right first costal cartilage close to the sternum (Fig. 19.1).

3. Left Brachiocephalic Vein

It is marked by two parallel lines 1.5 cm apart, drawn from the medial end of the left clavicle to the lower border of the first right costal cartilage. It crosses the left sternoclavicular joint and the upper half of the manubrium (Fig. 19.1).

Trace superior vena cava from level of first right costal cartilage where it is formed by union of left and right brachiocephalic veins till the third costal cartilage where it opens into right atrium. Trace the ascending aorta from the vestibule of left ventricle upwards between superior vena cava and pulmonary trunk. Arch of aorta is seen above the bifurcation of pulmonary trunk. Cut ligamentum arteriosum as it connects the left pulmonary artery to the arch of aorta. Trace the left recurrent laryngeal nerve to the medial aspect of arch of aorta. Lift the side of oesophagus forwards to expose the anterior surface of the descending aorta. Lift the diaphragm forwards and expose the aorta in the inferior part of the posterior mediastinum.

Relations of Superior Vena Cava

A. Anterior: (i) Chest wall, (ii) internal thoracic vessels, (iii) anterior margin of the right lung and pleura, (iv) the vessel is covered by pericardium in its lower half (Fig. 19.3).

B. Posterior: (i) Trachea and right vagus (postero medial to the upper part of the vena cava), (ii) root of right lung posterior to the lower part.

C. Medial: (i) Ascending aorta, (ii) brachiocephalic artery.
D. Lateral: (i) Phrenic nerve with accompanying vessels, (ii) right pleura and lung.

Tributaries

1. The azygos vein arches over the root of the right lung and opens into the superior vena cava at the level of the second costal cartilage, just before the latter enters the pericardium.

2. Several small mediastinal and pericardial veins drain into the vena cava.

Development

1. The upper half of the superior vena cava up to the opening of the azygos vein, develops from the right anterior cardinal vein.

2. The lower half, below the opening of the azygos vein, develops from the right common cardinal vein.

When the superior vena cava is obstructed above the opening of the azygos vein, the venous blood of the upper half of the body is returned through the femoral vein; and the superior veins are dilated on the chest up to the costal margin.

When the superior vena cava is obstructed below the opening of the azygos veins, the blood is returned through the inferior vena cava via the femoral vein; and the superior veins are dilated on both the chest and abdomen up to the saphenous
opening in the thigh. The superficial vein connecting the lateral thoracic vein with the superficial vein is known as the thoracoepigastric.

In cases of mediastinal syndrome, the signs of superior vena caval obstruction are the first to appear.

**THE AORTA**

The aorta is the great arterial trunk which receives oxygenated blood from the left ventricle and distributes it to all parts of the body. It is studied in three parts: (i) the ascending aorta, (ii) the arch of the aorta, and (iii) the descending aorta, epigastric.

### Surface Marking

**Ascending Aorta**

1. First mark the aortic valve by a slightly oblique line 2.5 cm long running downwards and to the right over the left half of the sternum beginning at the level of the lower border of the left third costal cartilage.

2. Then mark the ascending aorta (Fig. 19.4) by two parallel lines 2.5 cm apart from the aortic orifice; it is to all parts of the body.

---

**Fig. 19.3:** Transverse section of the thorax passing through the fifth thoracic vertebra.

**Fig. 19.4:** Surface marking of some arteries of thorax.
Arch of the Aorta

Arch of the aorta lies behind the lower half of the manubrium sterni. Its upper convex border is marked by a line which begins at the right end of the sternal angle, arches upwards and to the left through the centre of the manubrium, and ends at the sternal end of the left second costal cartilage. Note that the beginning and the end of the arch lie at the same level. When marked on the surface as described above the arch looks much smaller than it actually is because of foreshortening.

Descending Thoracic Aorta

Descending thoracic aorta is marked by two parallel lines 2.5 cm apart, which begin at the sternal end of the left second costal cartilage, pass downwards and medially, and end in the median plane 2.5 cm above the transpyloric plane.

Brachiocephalic Artery

Brachiocephalic artery is marked by a broad line extending from the centre of the manubrium to the right sternoclavicular joint.

Left Common Carotid Artery

The thoracic part of this artery is marked by a broad line extending from a point a little to the left of the centre of the manubrium to the left sternoclavicular joint.

Left Subclavian Artery

The thoracic part of the left subclavian artery is marked by a broad vertical line along the left border of the manubrium a little to the left of the left common carotid artery.

Arch of the Aorta

### Origin and Course

The ascending aorta arises from the upper end of the left ventricle. It is about 5 cm long and is enclosed in the pericardium (Fig. 19.2).

It begins behind the left half of the sternum at the level of the lower border of the third costal cartilage. It runs upwards, forwards and to the right and becomes continuous with the arch of the aorta at the sternal end of the upper border of the second right costal cartilage.

At the root of the aorta there are three dilatations of the vessel wall called the aortic sinuses. The sinuses are anterior, left posterior and right posterior.

### Relations

**Anterior:** (i) Sternum, (ii) left lung and pleura, infundibulum of the right ventricle, (iv) root of pulmonary trunk, and (v) right auricle (Fig. 19.1).

**Posterior:** (i) Transverse sinus of pericardium, left atrium, (iii) right pulmonary artery, and (iv) right bronchus (Fig. 19.3).

**To the right:** (i) Superior vena cava, and (ii) right atrium.

**To the left:** (i) Pulmonary trunk above, and (ii) left atrium below.

### Branches

1. The right coronary artery arises from the anterior aortic sinus, while the left coronary emerges from the left posterior aortic sinus (Fig. 18.19).
2. Left coronary artery arises from the left posterior aortic sinus.

---

### Arch of the Aorta

Arch of the aorta is the continuation of the ascending aorta. It is situated in the superior mediastinum behind the lower half of the manubrium sterni.

### Course

1. It begins behind the upper border of the second sternochondral joint (Figs 17.2-17.4).
2. It runs upwards, backwards and to the left across the left side of the bifurcation of the trachea. The it passes downwards behind the left bronchus an on the left side of the body of the fourth thoracic vertebra. It thus arches over the root of the left lung.
3. It ends at the lower border of the body of the fourth thoracic vertebra by becoming continuous with the descending aorta.

Thus the beginning and the end of the aorta are at the same level although it begins anteriorly and ends posteriorly.

### Relations

**Anteriorly and to the Left**

1. Four nerves including from before backward: (i) left phrenic, (ii) left cervical cardiac branch < left sympathetic chain, and (iv) left vagus (Fig. 19.5)
2. Left superior intercostal vein, deep to the phrenic nerve and superficial to the vagus nerve.
3. Left pleura and lung.
4. Remains of thymus.
B. Posteriorly and to the Right
1. Trachea, with the deep cardiac plexus and the tracheobronchial lymph nodes.
2. Oesophagus.
3. Left recurrent laryngeal nerve.
4. Thoracic duct.
5. Vertebral column.

C. Superior
1. Three branches of the arch of the aorta: (i) brachiocephalic, (ii) left common carotid, and (iii) left subclavian arteries (Fig. 19.6).
2. All three arteries are crossed close to their origin by the left brachiocephalic vein.

D. Inferior
1. Bifurcation of the pulmonary trunk.
2. Left bronchus.
3. Ligamentum arteriosum with superficial cardiac plexus on it.
4. Left recurrent laryngeal nerve.

**Branches**

1. Brachiocephalic artery which divides into the right common carotid and right subclavian arteries (Fig. 19.2).
2. Left common carotid artery.
3. Left subclavian artery.
4. Occasionally: (i) the thyroidea ima, (iii) or vertebral artery may arise from it.
1. **Aortic knuckle.** In PA view of radiographs of the chest, the arch of the aorta is seen as a projection beyond the left margin of the mediastinal shadow. The projection is called the aortic knuckle. It becomes prominent in old age.

2. **Coarctation of the aorta** is a localized narrowing of the aorta opposite to or just beyond the attachment of the ductus arteriosus. An extensive collateral circulation develops between the branches of the subclavian arteries and those of the descending aorta. These include the anastomoses between the anterior and posterior intercostal arteries. These arteries enlarge greatly and produce a characteristic notching on the ribs.

3. **Ductus arteriosus, ligamentum arteriosum and patent ductus arteriosus,** during fetal life, the **ductus arteriosus** is a short wide channel connecting the beginning of the left pulmonary artery with the arch of the aorta immediately distal to the origin of the left subclavian artery. It conducts most of the v blood from the right ventricle into the aorta, thus shortcircuiting the lungs. After birth it is closed functionally within about a week and anatomically within about 8 weeks. The remnants of the ductus form a fibrous band called the **ligamentum arteriosum.** The left recurrent laryngeal nerve hooks around the ligamentum arteriosum.

   The ductus may remain patent after birth. The condition is called **patent ductus arteriosus** and may cause serious problems. The condition can be surgically treated.

4. **Aortic aneurysm** is a localized dilatation of the aorta which may press upon the surrounding structures and cause the mediastinal syndrome.
hi
DESCENDING THORACIC AORTA

Descending thoracic aorta is the continuation of the arch of the aorta. It lies in the posterior mediastinum (Fig. 17.4).

Course
1. It begins on the left side of the lower border of the body of the fourth thoracic vertebra.
2. It descends with an inclination to the right and terminates at the lower border of the twelfth thoracic vertebra.
Relations

Anterior: (i) Root of left lung, (ii) pericardium and heart, (iii) oesophagus in the lower part, and (iv) diaphragm.

Posterior: (i) Vertebral column, and (ii) hemiazygos veins.

To the right side: (i) Oesophagus in the upper part, (ii) azygos vein, (iii) thoracic duct, and (iv) right lung and pleura (Fig. 19.3).

To the left side: Left lung and pleura.

Branches

1. Nine posterior intercostal arteries on each side for the third to eleventh intercostal spaces.
2. The subcostal artery on each side.
1. Two left bronchial arteries. The upper left artery may give rise to the right bronchial artery which usually arises from the third right posterior intercostal artery.
2. Oesophageal branches, supplying the middle one-third of the oesophagus.
3. Pericardial branches, to the posterior surface of the pericardium.
4. Mediastinal branches, to lymph nodes and areolar tissue of the posterior mediastinum.
5. Superior phrenic arteries to the posterior part of the superior surface of the diaphragm. Branches of these arteries anastomose with those of the musculophrenic and pericardiophrenic arteries.

**PULMONARY TRUNK**

**Surface Marking**

1. First mark the pulmonary valve by a horizontal line 2.5 cm long, mainly along the upper border of the left third costal cartilage and partly over the adjoining part of the sternum (Fig. 18.18).
2. Then mark the pulmonary trunk by two parallel lines 2.5 cm apart from the pulmonary orifice upwards to the left second costal cartilage (Fig. 18.6).

The wide pulmonary trunk starts from the summit of infundibulum of right ventricle. Both the ascending aorta and pulmonary trunk are enclosed in a
common sleeve of serous pericardium, in front of transverse sinus of pericardium. Pulmonary trunk carrying deoxygenated blood overlies the beginning of ascending aorta. It courses to the left and divides into right and left pulmonary arteries under the concavity of aortic arch at the level of sternal angle (Figs 19.2, 19.3). The right pulmonary artery courses to the right behind ascending aorta, and superior vena cava and anterior to oesophagus to become part of the root of the lung. It gives off its first branch to the upper lobe before entering the hilum. Within the lung the artery descends posterolateral to the main bronchus and divides like the bronchi into lobar and segmental arteries. The left pulmonary artery passes to the left anterior to descending thoracic aorta to become part of the root of the left lung. At its beginning, it is connected to the inferior aspect of arch of aorta by ligamentum arteriosus, a remnant of ductus arteriosus. Rest of the course is same as of the right branch.

DEVELOPMENT OF ARTERIES

Fused heart tubes form ventral aorta, which forms the aortic sac. Aortic sac gets divided by spiral septum into ventral part, the aorta and dorsal part the pulmonary trunk. The aorta forms right and left horns which get connected to respective dorsal aorta by six arch arteries. Below this level the two dorsal aortae fuse to form single aorta (Fig. 19.7).

Neural crest cells get intermingled in the spiral septum as well as in the processes forming the face. So defects of heart and face may appear together.

1. Arch of aorta is formed from ventral part of aortic sac, left fourth arch artery and left dorsal aorta upto seventh cervical intersegmental artery.
2. Descending aorta is formed by left dorsal aorta below the fourth arch artery and by fused dorsal aortae.
3. Brachiocephalic artery is formed from right horn of aortic sac wherein third and fourth arch arteries open.
4. Common carotid is formed from proximal half of third arch artery.
5. External carotid artery is new branch from third arch.
6. Right subclavian artery is formed by proximal part of right fourth arch artery, part of right dorsal aorta and distal part of right seventh cervical intersegmental artery.
7. Left subclavian artery is formed only by seventh left intersegmental artery.

DEVELOPMENT OF VEINS

To begin with the veins draining the embryo are the cardinal veins. These are anterior cardinal vein from the cephalic part of the embryo, the posterior cardinal vein from caudal part.

Anterior and posterior cardinal veins join to form short common cardinal veins which in turn drain

The oblique anastomosis between two anterior cardinal veins develops into the left brachiocephalic
into the sinus venosus.

Veins though appear symmetrically, retrogress from the left side with the result, the main veins get formed on the right side. The reverse is true for the arteries.

vein. The terminal portion of left posterior cardinal vein opening into the left brachiocephalic vein forms the left superior intercostal vein. Proximal portion of right anterior cardinal vein with the right common cardinal vein forms the superior vena cava.
Trachea or windpipe is the patent tube for passage of air to and from the lungs. In contrast, oesophagus lying behind the trachea opens only while drinking or eating. Thoracic duct brings the lymph from major part of the body to the root of the neck.
Remove the posterior surface of the parietal pericardium between the right and left pulmonary veins. This uncovers the anterior surface of the oesophagus in the posterior mediastinum.

Find the azygos vein and its tributaries on the vertebral column to the right of the oesophagus. Find and follow the thoracic duct on the left of azygos vein.

Identify the sternal, sternocostal, interchondral and costochondral joints in the anterior aspect of chest wall which was reflected downwards.

Expose the ligaments which unite the heads of the ribs to the vertebral bodies and intervertebral discs.

---

**THE TRACHEA**

The trachea is a wide tube lying more or less in the midline, in the lower part of the neck and in the superior mediastinum. Its upper end is continuous with the lower end of the larynx. At its lower end the trachea ends by dividing into the right and left principal bronchi (Fig. 20.1).

The trachea is 10 to 15 cm in length. Its external diameter measures about 2 cm in males and about 1.5 cm in females. The lumen is smaller in the living than in the cadaver. It is about 3 mm at one year of age. During childhood it corresponds to the age in years, with a maximum of about 12 mm in adults.
The upper end of the trachea lies at the lower border of the cricoid cartilage, opposite the sixth cervical vertebra. In the cadaver its bifurcated lower end lies at the lower border of the fourth thoracic vertebra, corresponding in front to the sternal angle. However, in living subjects, in the erect posture, the bifurcation lies at the lower border of the sixth thoracic vertebra and descends still further during inspiration.

Over most of its length the trachea lies in the median plane, but near the lower end it deviates
slightly to the right. As it runs downwards, the trachea passes slightly backwards following the curvature of the spine.

**Surface Marking**

7. **Thoracic Part of Trachea**

It is marked by two parallel lines 2 cm apart, drawn from the lower border of the cricoid cartilage to the sternal angle, inclining slightly to the right (Fig. 20.1).

2. **Right Bronchus**

It is marked by a broad line running downwards and to the right for 2.5 cm from the lower end of the trachea to the sternal end of the right third costal cartilage.

3. **Left Bronchus**

It is marked by a broad line running downwards and to the left for 5 cm from the lower end of the trachea to the left third costal cartilage 4 cm from the median plane.

**Relations of the Thoracic Part**

A. **Anteriorly:** (i) Manubrium sterni, (ii) sternothyroid muscles, (iii) remains of the thymus, (iv) the left brachiocephalic and inferior thyroid veins, (v) aortic arch, brachiocephalic and left common carotid arteries, (vi) deep cardiac plexus, and (vii) some lymph nodes (Fig. 19.5).

B. **Posteriorly:** (i) Oesophagus, and (ii) vertebral column.

C. **On the right side:** (i) Right lung and pleura, (ii) right vagus, and (iii) azygos vein (Fig. 20.2).

D. **On the left side:** (i) Arch of aorta, left common carotid and left subclavian arteries, and (ii) left recurrent laryngeal nerve (Fig. 20.3).

For relations of cervical part see Vol. 3 of this book.

**Structure**

The trachea has a fibroelastic wall supported by a cartilaginous skeleton formed by C-shaped rings. The rings are about 16-20 in number and make the tube convex anterolaterally. Posteriorly there is a gap which is closed by a fibroelastic membrane and contains transversely arranged smooth muscle known as the trachealis. The lumen is lined by ciliated columnar epithelium and contains many mucous and serous glands.

Arterial supply: Inferior thyroid arteries.

Venous drainage: Into the left brachiocephalic vein.

Lymphatic drainage: To the pretracheal and paratracheal nodes.

**Nerve supply**

1. **Parasympathetic:** Nerves through vagi and recurrent laryngeal nerves. It is: (i) sensory and secretomotor to the mucous membrane, and (ii) motor to the trachealis muscle.
2. **Sympathetic:** Fibres from the middle cervical ganglion reach it along the inferior thyroid arteries and are vasomotor.

**CLINICAL ANATOMY**

1. In radiographs, the trachea is seen as a vertical translucent shadow due to the contained air in front of the cervicothoracic spine.
2. Clinically the trachea is palpated in the suprasternal notch. Normally it is median in position. Shift of the trachea to any side indicates a mediastinal shift.
3. During swallowing when the larynx is elevated, the trachea elongates by stretching because the tracheal bifurcation is not permitted to move by the aortic arch. Any downward pull due to sudden and forced inspiration, or aortic aneurysm will produce the physical sign known as 'tracheal tug'.
5. As the tracheal rings are incomplete posteriorly the oesophagus can dilate during swallowing. This also allows the diameter of the trachea to be controlled by the trachealis muscle. This muscle narrows the calibre of the tube, compressing the contained air if the vocal cords are closed. This increases the explosive force of the blast of compressed air, as occurs in coughing and sneezing.
6. Mucous secretions help in trapping inhaled foreign particles, and the soiled mucus is then
expelled by coughing. The cilia of the mucous membrane beat upwards, pushing the mucus towards the pharynx.

7. The trachea may get compressed by pathological enlargements of the thyroid, the thymus, lymph nodes and the aortic arch. This causes dyspnoea, irritative cough, and often a husky voice.

**THE OESOPHAGUS**

The oesophagus is a narrow muscular tube, forming the food passage between the pharynx and stomach. It extends from the lower part of the neck to the upper part of the abdomen (Fig. 20.4). The oesophagus is about 25 cm long. The tube is flattened anteroposteriorly and the lumen is kept collapsed; it dilates only during the passage of the food bolus. The pharyngo-oesophageal junction is the narrowest part of the alimentary canal except for the vermiform appendix (Fig. 17.3).

The oesophagus begins in the neck at the lower border of the cricoid cartilage where it is continuous with the lower end of the pharynx.

It descends in front of the vertebral column through the superior and posterior parts of the mediastinum, and pierces the diaphragm at the level of tenth thoracic vertebra. It ends by opening into the stomach at its cardiac end at the level of eleventh thoracic vertebra.
Curvatures
In general, the oesophagus is vertical, but shows slight curvatures in the following directions. There are two side to side curvatures, both towards the left (Fig. 17.4). One is at the root of the neck and the other near the lower end. It also has anteroposterior curvatures that correspond to the curvatures of the cervicothoracic spine.

Constrictions
Normally the oesophagus shows 4 constrictions at the following levels.
1. At its beginning, 15 cm from the incisor teeth.
2. Where it is crossed by the aortic arch, 22.5 cm from the incisor teeth.
3. Where it is crossed by the left bronchus, 27.5 cm from the incisor teeth.
4. Where it pierces the diaphragm 37.5 cm from the incisor teeth.

The distances from the incisor teeth are important in passing instruments into the oesophagus.

For sake of convenience the relations of the oesophagus may be studied in three parts: cervical, thoracic and abdominal. The relations of the cervical part are described in Vol. 3, and those of the abdominal part in Vol. 2 of this book.

Surface Marking
The oesophagus is marked by two parallel lines 2.5 cm apart by joining the following points.

1. Two points 2.5 cm apart at the lower border of the cricoid cartilage across the median plane (Fig. 20.5).
2. Two points 2.5 cm apart at the root of the neck a little to the left of the median plane.
3. Two points 2.5 cm apart at the sternal angle across the median plane.
4. Two points 2.5 cm apart at the left seventh costal cartilage 2.5 cm from the median plane.

Relations of the Thoracic Part of the Oesophagus
A. Anterior: (i) Trachea, (ii) right pulmonary artery, (iii) left bronchus, (iv) pericardium with left atrium, and (v) the diaphragm (Figs 20.2, 20.3).
B. Posteriorly: (i) Vertebral column, (ii) right posterior intercostal arteries, (iii) thoracic duct, (iv) azygos vein with the terminal parts of the hemiazygos veins.
C. To the right: (i) Right lung and pleura, (ii) azygos vein, and (iii) the right vagus (Fig. 20.6).
D. To the left: (i) Aortic arch, (ii) left subclavian artery, (iii) thoracic duct, (iv) left lung and pleura, and (v) left recurrent laryngeal nerve, all in the superior mediastinum (Figs 19.3, 20.8).

In the posterior mediastinum, it is related to: (i) the descending thoracic aorta, and (ii) the left lung and mediastinal pleura (Figs 17.4, 20.6).

Arterial Supply

1. The cervical part including the segment up to the arch of aorta is supplied by the inferior thyroid arteries.
1. The thoracic part is supplied by the oesophageal branches of the aorta.
2. The abdominal part is supplied by the oesophageal branches of the left gastric artery.

**Venous Drainage**

Blood from the upper part of the oesophagus drains into the brachiocephalic veins; from the middle part it goes to the azygos veins; and from the lower end it goes to the left gastric vein. The lower end of the oesophagus is one of the sites of portosystemic anastomoses.

**Lymphatic Drainage**

The cervical part drains into the deep cervical nodes: the thoracic part to the posterior mediastinal nodes; and the abdominal part to the left gastric nodes.

**Nerve Supply**

_A. Parasympathetic nerves._ The upper half of the oesophagus is supplied by the recurrent laryngeal nerves, and the lower half by the oesophageal plexus formed mainly by the two vagi. Parasympathetic nerves are sensory, motor and secretomotor to the oesophagus.

_B. Sympathetic nerves._ For the upper half of the oesophagus, the fibres come from the middle cervical ganglion and run on the inferior thyroid arteries. For the lower half, the fibres come directly from the upper four thoracic ganglia, and take part in forming the oesophageal plexus before supplying the oesophagus. Sympathetic nerves are vasomotor.

The _oesophageal plexus_ is formed mainly by the parasympathetic through vagi but sympathetic fibres are also present. Towards the lower end of the oesophagus the vagal fibres form the anterior and posterior gastric nerves which enter the abdomen through the oesophageal opening of the diaphragm.

**HISTOLOGY**

Mucous membrane—Epithelial lining is stratified squamous non-keratinised in nature. Lamina propria consists of loose connective tissue with papillae.

Muscularis mucosae is distinct in lower part and formed by longitudinal muscle fibres.

Submucosa contains mucus-secreting oesophageal glands.

Muscularis externa is composed of striated muscle in upper third; mixed type in middle third and smooth muscles in lower third. Outer layer comprises longitudinal coat and inner is of circular coat of muscle fibres.

Adventitia is the connective tissue with capillaries.
1. In portal hypertension, the communications between the portal and systemic veins draining the lower end of the oesophagus dilate. These dilatations are called *oesophageal varices*. Rupture of these varices can cause serious haematemesis or vomiting of blood. The oesophageal varices can be visualized radiographically by barium swallow: they produce worm-like shadows.

2. Left atrial enlargement as in mitral stenosis can also be visualized by barium swallow. The enlarged atrium causes a shallow depression on the front of the oesophagus. Barium swallow also helps in the diagnosis of oesophageal strictures, carcinoma and achalasia cardia.

3. The normal indentations on the oesophagus should be kept in mind during oesophagoscopy (Fig. 20.7).

4. The lower end of the oesophagus is normally kept closed. It is opened by the stimulus of a food bolus. In case of neuromuscular incoordination, the lower end of the oesophagus fails to dilate with the arrival of food which, therefore, accumulates in the oesophagus. This condition of neuromuscular incoordination characterized by inability of the oesophagus to dilate is known as 'achalasia cardia'.

5. Improper separation of the trachea from the oesophagus during development gives rise to tracheo-oesophageal fistula.

6. Compression of the oesophagus in cases of mediastinal syndrome causes dysphagia (or difficulty in swallowing).

---

**The Thoracic Duct**

The thoracic duct is the largest lymphatic vessel in the body. It extends from the upper part of the abdomen to the lower part of the neck, crossing the posterior and superior parts of the mediastinum. It is about 45 cm long. It has a beaded appearance because of the presence of many valves in its lumen (Fig. 20.8).

**Course**

The thoracic duct begins as a continuation of the upper end of the cisterna chyli near the lower border of the twelfth thoracic vertebra and enters the thorax through the aortic opening of the diaphragm. It then ascends through the posterior mediastinum crossing from the right side to the left at the level of the fifth thoracic vertebra. It then runs through the superior mediastinum along the edge of the oesophagus and reaches the neck.

In the neck, it arches laterally at the level of the transverse process of seventh cervical vertebra. Finally it descends in front of the first part of the left subclavian artery and ends by opening into the angle of junction between the left subclavian and left internal jugular veins.

**Surface Marking**

The thoracic duct is marked by joining the following points.

1. A point 2 cm above the transpyloric plane just to the right of the median plane (Fig. 20.9).
1. A point just above the sternal angle 1.3 cm to the left of the median plane.
2. A point 3 cm above the left clavicle 2 cm from the median plane.
3. Lastly it arches laterally for 1.3 cm to end behind the clavicle.

Relations

A. At the Aortic Opening of the Diaphragm
   Anteriorly: Diaphragm
Posteriorly: Vertebral column
To the right: Azygos vein To the left: Aorta

B. In the Posterior Mediastinum (Figs 19.3, 19.5)
Anteriorly: (i) Diaphragm, (ii) oesophagus, and (iii) right pleural recess
Posteriorly: (i) Vertebral column, (ii) right posterior intercostal arteries, (iii) terminal parts of the hemiazygos veins (Figs 20.4, 20.6).
To the right: Azygos vein
To the left: Descending thoracic aorta.

C. In the Superior Mediastinum
Anteriorly: (i) Arch of aorta, and (ii) the origin of the left subclavian artery.
Posteriorly: Vertebral column. To the right: Oesophagus To the left: Pleura.

D. In the Neck

The thoracic duct forms an arch rising about 3-4 cm above the clavicle. The arch has the following relations.

Anteriorly: (i) Left common carotid artery, (ii) left vagus, and (iii) left internal jugular vein.

Posteriorly: (i) Vertebral artery and vein, (ii) sympathetic trunk, (iii) thyrocervical trunk and its branches, (iv) left phrenic nerve, (v) medial border of the scalenus anterior, (vi) prevertebral fascia covering all the structures mentioned, and (vii) the first part of the left subclavian artery.

Tributaries

The thoracic duct receives lymph from, roughly, both halves of the body below the diaphragm and the left half above the diaphragm (Fig. 20.10).

In the thorax, the thoracic duct receives lymph vessels from the posterior mediastinal nodes and from small intercostal nodes. At the root of the neck, efferent vessels of the nodes in the neck form the left jugular trunk, and those from nodes in the axilla form the left subclavian trunk. These trunks end either in the thoracic duct or in one of the large veins. The left
mediastinal trunk drains lymph from the left half of the thorax, usually it ends in the brachiocephalic vein, but may end in the thoracic duct.

1. The thoracic duct may break up into a number of small vessels just before its termination.

2. It may divide in the middle of its course into two vessels which soon unite. Sometimes it may form a plexiform network in the middle.

3. Occasionally it divides in its upper part into two branches, right and left. The left branch ends in the usual manner, and the right opens into the right subclavian vein along with the right lymphatic duct.
Surface marking is the projection of deeper structures on the surface of body.

**SURFACE MARKING**

The bony and soft tissue surface landmarks have been described in Chapter 12. The surface marking of important structures is described here.

- **A. Pleura** (Fig. 15.9)
- **B. Lungs** (Fig. 16.5)
- **C. Heart** (Fig. 18.8)
- **D. Cardiac valves** (Fig. 18.18)

**Arteries**

**Internal Mammary (Thoracic) Artery**

It is marked by joining the following points (Fig. 14.10).

(i) A point 1 cm above the sternal end of the clavicle, 3.5 cm from the median plane.
(ii) Points marked over the upper 6 costal cartilages at a distance of 1.25 cm from the lateral sternal border.
(iii) The last point is marked in the sixth space 1.25 cm from the lateral sternal border.
Pulmonary Trunk

(i) First mark the pulmonary valve by a horizontal line 2.5 cm long, mainly along the upper border of the left 3rd costal cartilage and partly over the adjoining part of the sternum (Fig. 18.18).
(ii) Then mark the pulmonary trunk by two parallel lines 2.5 cm apart from the pulmonary orifice upwards to the left 2nd costal cartilage (Fig. 18.6).

**Ascending Aorta**

(i) First mark the aortic orifice by a slightly oblique line 2.5 cm long running downwards and to the right over the left half of the sternum beginning at the level of the lower border of the left 3rd costal cartilage (Fig. 18.18).

(ii) Then mark the ascending aorta by two parallel lines 2.5 cm apart from the aortic orifice upwards to the right half of the sternal angle (Fig. 19.4).

**Arch of the Aorta**

Arch of the aorta lies behind the lower half of the manubrium sterni. Its upper convex border is marked by a line which begins at the right end of the sternal angle, arches upwards and to the left through the centre of the manubrium, and ends at the sternal end of the left second costal cartilage. Note that the beginning and the end of the arch lie at the same level. When marked on the surface as described above the arch looks much smaller than it actually is because of foreshortening (Fig. 19.4).

**Descending Thoracic Aorta**

Descending thoracic aorta is marked by two parallel lines 2.5 cm apart, which begin at the sternal end of the left second costal cartilage, pass downwards and
medially, and end in the median plane 2.5 cm above the transpyloric plane.

**Brachiocephalic Artery**

Brachiocephalic artery is marked by a broad line extending from the centre of the manubrium to the right sternoclavicular joint (Fig. 19.4).

**Left Common Carotid Artery**

The thoracic part of this artery is marked by a broad line extending from a point a little to the left of the centre of the manubrium to the left sternoclavicular joint.

**Left Subclavian Artery**

The thoracic part of the left subclavian artery is marked by a broad vertical line along the left border of the manubrium a little to the left of the left common carotid artery.

**Veins**

**Superior Vena Cava**

Superior vena cava is marked by two parallel lines 2 cm apart, drawn from the lower border of the right first costal cartilage to the upper border of the third right costal cartilage, overlapping the right margin of the sternum (Fig. 19.1).

**Right Brachiocephalic Vein**

It is marked by two parallel lines 1.5 cm apart, drawn from the medial end of the right clavicle to the lower border of the right first costal cartilage close to the sternum (Fig. 19.1).

**Left Brachiocephalic Vein**

It is marked by two parallel lines 1.5 cm apart, drawn from the medial end of the left clavicle to the lower border of the first right costal cartilage. It crosses the left sternoclavicular joint and the upper half of the manubrium (Fig. 19.1).

**Certain Viscera**

**Trachea (Thoracic Part)**

Trachea is marked by two parallel lines 2 cm apart, drawn from the lower border of the cricoid cartilage to the sternal angle, inclining slightly to the right (Fig. 20.1).

**Right Bronchus**

Right bronchus is marked by a broad line running downwards and to the right for 2.5 cm from the lower end of the trachea to the sternal end of the right third costal cartilage.

**Left Bronchus**

Left bronchus is marked by a broad line running downwards and to the left for 5 cm from the lower end of the trachea to the left third costal cartilage 4 cm from the median plane.

**Oesophagus**

It is marked by two parallel lines 2.5 cm apart by joining the following points (Fig. 20.5).

(i) Two points 2.5 cm apart at the lower border of the cricoid cartilage across the median plane.
(ii) Two points 2.5 cm apart at the root of the neck a little to the left of the median plane.
(iii) Two points 2.5 cm apart at the sternal angle across the median plane.
(iv) Two points 2.5 cm apart at the left 7th costal cartilage 2.5 cm from the median plane.

**Thoracic Duct**

It is marked by joining the following points (Fig. 20.9).

(i) A point 2 cm above the transpyloric plane slightly to the right of the median plane.
(ii) A second point 2.5 cm above the left clavicle 2 cm from the median plane.
(iii) A third point just above the sternal angle 1.3 cm to the left of the median plane.

Radiography of chest is done to detect a very common disease-the tuberculosis of the lungs.

**RADIOGRAPHY**

The most commonly taken radiographs are described as posteroanterior (or PA) views. X-rays travel from posterior to the anterior side. A study of such radiographs gives information about the lungs, the diaphragm, the mediastinum, the trachea, and the skeleton of the region (Fig. 21.1).

Following structures have to be examined in posteroanterior view of the thorax.

**7. Soft Tissues**

Nipples in both the sexes may be seen over the lung fields. The female breasts will also be visualised over the lower part of the lung fields. The extent of the overlap varies according to the size and pendulance of the breasts.
2. **Bones**

The bones of the vertebrae are partially visible. Costotransverse joints are seen on each side. The posterior parts of the ribs are better seen because of the large amounts of calcium contained in them. The ribs get wider and thinner as they pass anteriorly. Costal cartilages are not seen unless these are calcified. The medial borders of the scapulae may overlap the periphery of the lung fields.

3. **Trachea**

Trachea is seen as air-filled shadow in the midline of the neck. It lies opposite the lower cervical and upper thoracic vertebrae (Fig. 21.1).

4. **Diaphragm**
Diaphragm casts dome-shaped shadows on the two sides. The shadow on the right side is little higher than on the left side. The angles where diaphragm meets the thoracic cage are the costophrenic angles—the right and the left. Under the left costophrenic angle is mostly the gas in the stomach, while under the right angle is the smooth shadow of the liver.

5. **Lungs**

The dense shadows are cast by the lung roots due to the presence of the large bronchi, pulmonary bronchial vessels and lymph nodes. The lungs readily permit the passage of the X-rays and are seen as translucent shadows during the full inspiration. Both blood vessels and bronchi are seen as series of
shadows radiating from the lung roots. The smaller bronchi are not seen. The lung is divided into three zones—upper zone is from the apex till the second costal cartilage. Middle zone extends from the second to the fourth costal cartilage. It includes the hilar region. Lower zone extends from the fourth costal cartilage till the bases of the lungs.

6. Mediastinum

Shadow is produced by the superimpositions of structures in the mediastinum. It is chiefly produced by the heart and the vessels entering or leaving the heart. The transverse diameter of heart is half the transverse diameter of the thoracic cage. During inspiration, heart descends down and acquires tubular shape. Right border of the mediastinal shadow is formed from above downwards by right brachiocephalic vein, superior vena cava, right atrium and inferior vena cava. The left border of mediastinal shadow is formed from above downwards by aortic arch (aortic knuckle), left margin of pulmonary trunk, left auricle and left ventricle. The inferior border of the mediastinal shadow blends with the liver and diaphragm.

Tomography

Tomography is a radiological technique by which radiograms of selected layers (depths) of the body can be made. Tomography is helpful in locating deeply situated small lesions which are not seen in the usual radiograms.
Appendix 2 at the end of the section on thorax gives a bird's eye view of the sympathetic component of the autonomic nervous system. The course of the typical and atypical intercostal nerves is also mentioned.

Five sample clinicoanatomical problems are solved. In the end, 20 sample multiple choice questions (MCQs) are given to test the knowledge and skill gained by the readers after studying various chapters of the book.

Autonomic Nervous System
The autonomic nervous system comprises sympathetic and parasympathetic components. Sympathetic is active during fright, flight or fight. During any of these activities, the pupils dilate, skin gets pale, blood pressure rises, blood vessels of skeletal muscles, heart, lungs and brain dilate. There is hardly any activity in the digestive tracts due to which the individual does not feel hungry. The person is tense and gets tired soon.

Parasympathetic has the opposite effects of sympathetic. This component is sympathetic to the digestive tract. In its activity digestion and metabolism of food occurs. Heart beats normally. Person is relaxed and can do creative work.

Autonomic nervous system is controlled by brainstem and cerebral hemispheres. These include reticular formation of brainstem, thalamic and hypothalamic nuclei, limbic lobe and prefrontal cortex including the ascending and descending tracts interconnecting these regions.

Sympathetic Nervous System
Sympathetic nervous system is the larger of the two components of autonomic nervous system. It consists of two ganglionated trunks, their branches, prevertebral ganglia, plexuses. It supplies all the viscera of thorax, abdomen and pelvis, including the blood vessels of head and neck, brain, limbs, skin.
and the sweat glands as well as arrector pilorum muscle of skin.

The preganglionic fibres are the axons of neurons situated in the lateral horns of T1-L2 segments of spinal cord. They leave spinal cord through their respective ventral roots, to pass in their nerve trunks, and beginning of ventral rami via white ramus communicans (WRC). There are 14 WRC on each side. These fibres can have following alternative routes:

i. They relay in the ganglion of the sympathetic trunks, postganglionic fibres pass via the grey communicans and get distributed to the blood vessels of muscles, skin, sweat glands and to arrector pili muscles (Fig. A2.1).

ii. These may pass through the corresponding ganglion and ascend to a ganglion higher before terminating in the above manner.

iii. These may pass through the corresponding ganglion and descend to a ganglion lower and then terminate in the above manner.

iv. These may synapse in the corresponding ganglia and pass medially to the viscera like heart, lungs, oesophagus.

v. These white rami communicans pass to corresponding ganglia and emerge from these as WRC (unrelayed) in the form of splanchnic nerves to supply abdominal and pelvic viscera after synapsing in the ganglia situated in the abdominal cavity.

Sympathetic trunk on either side of the body extends from cervical region to the coccygeal region where both trunks fuse to form a single ganglion impar. It has cervical, thoracic, lumbar, sacral and coccygeal parts.

**Thoracic Part of Sympathetic Trunk**

There are usually 11 ganglia on the sympathetic trunk of thoracic part. The first ganglion lies on neck
Fig. A2.1: Pathways of sympathetic and somatic nerves. splanchnic afferent fibres (blue); sympathetic preganglionic efferent fibres (red); sympathetic preganglionic efferent fibres (red dotted); somatic efferent fibres (black); somatic afferent fibres (blue).
of 1st rib and is usually fused with inferior cervical ganglion and forms stellate ganglion. The lower ones lie on the heads of the ribs. The sympathetic trunk continues with its abdominal part by passing behind the medial arcuate ligament.

The ganglia are connected with the respective spinal nerves via the white ramus communicans (from the spinal nerve to the ganglion) and the grey ramus communicans (from the ganglion to the spinal nerve, i.e. ganglion gives grey).

**Branches**

1. Grey rami communicans to all the spinal nerves, i.e. T1-T12. The postganglionic fibres pass along the spinal nerves to supply cutaneous blood vessels, sweat glands and arrector pili muscles.

2. White rami communicans from upper 4-6 ganglia travel up to the cervical part of sympathetic trunk of relay in the three cervical ganglia. Fibres from the lower thoracic ganglia T10-L2 pass down as preganglionic fibres to relay in the lumbar or sacral ganglia.
1. The first five ganglia give postganglionic fibres to heart, lungs, aorta and oesophagus.
2. Lower eight ganglia give fibres which are preganglionic (unrelayed) for the supply of abdominal viscera. These are called as splanchnic (visceral) nerves.
   - Ganglia 5-9 give fibres which constitute greater splanchnic nerve.
   - Ganglia 9-10 give fibres that constitute lesser splanchnic nerve.
   - Ganglion 11 gives fibres that constitute lowest splanchnic nerve.

**Nerve Supply of Heart Conveyed by the Cardiac Plexuses**

Preganglionic sympathetic neurons are located in lateral horns T1-T5 segments of spinal cord. These fibres pass along the respective ventral roots of thoracic nerves, to synapse with the respective ganglia of the sympathetic trunk. After relay the postganglionic fibres form thoracic branches which intermingle with the vagal fibres, to form cardiac plexus.
Some fibres from T1-T5 segments of spinal cord reach their respective ganglia. These fibres then travel up to the cervical part of the sympathetic chain and relay in superior, middle and inferior cervical ganglia. After relay, the postganglionic fibres form the three cervical cardiac nerves. Preganglionic parasympathetic neurons for the supply of heart are situated in the dorsal nucleus of vagus nerve. Sympathetic activity increases the heart rate. Larger branches of coronary are mainly supplied by sympathetic. It causes vasodilatation of coronary arteries. Impulses of pain travel along sympathetic fibres. These fibres pass mostly through left sympathetic trunk and reach the spinal cord via T1-T5 spinal nerves. Thus the pain may be referred to the area of skin supplied by T1-T5 nerves, i.e. retrosternal, medial side of the upper limbs. Since one is more conscious of impulses coming from skin than the viscera one feels as if the pain is in the skin. This is the basis of the referred pain.

Smaller branches of coronary artery are supplied by parasympathetic nerves. These nerves are concerned with slowing of the cardiac cycle.

The nerves reach the heart by two plexuses:

(a) **Superficial Cardiac Plexus**

Superficial cardiac plexus is formed by the following, (i) Superior cervical cardiac branch of left sympathetic trunk: (ii) Inferior cervical cardiac branch of left vagus nerve.

(b) **Deep Cardiac Plexus**

Deep cardiac plexus consists of two halves which are interconnected and lie anterior to bifurcation of trachea (Table A2.1).

Branches from the cardiac plexus give extensive branches to pulmonary plexuses, right and left coronary plexuses. Branches from the coronary plexuses supply both the atria and the ventricles. Left ventricle gets richer nerve supply because of its larger size.

---

**Lungs**

The lungs are supplied from the anterior and posterior pulmonary plexuses. Anterior plexus is an extension of deep cardiac plexus. The posterior is formed from branches of vagus and T2-T5 sympathetic ganglia. Small ganglia are found on these nerves for the relay of parasympathetic brought via vagus nerve fibres. Parasympathetic is broncho-constrictor or motor whereas sympathetic is inhibitory. Sympathetic stimulation causes relaxation of smooth muscles of bronchial tubes or bronchodilator. The pressure of inspired air also causes bronchodilatation.

---

**TYPICAL INTERCOSTAL NERVE**

Typical intercostal nerves are any of the nerves belonging to 3rd to 6th intercostal spaces.

**Beginning:** Typical thoracic spinal nerve after it has given off dorsal primary ramus or dorsal ramus is called the intercostal nerve. It runs in the intercostal space, i.e. between the lower border of rib above and upper border of rib below.

**Course:** Typical intercostal nerve enters the posterior part of intercostal space by passing behind the posterior intercostal vessels. So the intercostal nerve lies lowest in the neurovascular bundle. The order from above downwards is vein, artery and nerve (VAN). At first the bundle runs between posterior intercostal membrane and subcostalis, then between inner intercostal and innermost intercostal and lastly between inner intercostal and sternocostalis muscles.

At the anterior end of intercostal space, the intercostal nerve passes in front of internal thoracic vessels, pierces internal intercostal muscle and anterior intercostal membrane to continue as anterior cutaneous branch which ends by dividing into medial and lateral cutaneous branches.

---

Branches

1. Communicating branches to the sympathetic ganglion close to the beginning of ventral ramus. The anterior ramus containing sympathetic fibres from lateral horn of spinal cord gives off a white ramus communicans to the sympathetic ganglion. These fibres get relayed in the ganglion. Some of these relayed fibres pass via grey ramus communicans to ventral ramus. Few pass backwards in the dorsal ramus and rest pass through the ventral ramus. These sympathetic fibres are sudomotor, pilomotor and vasomotor to the skin and vasodilator to the skeletal vessels.

2. Before the angle, nerve gives a collateral branch that runs along the upper border of lower rib. This branch supplies intercostal muscles, costal pleura and periosteum of the rib.

3. Lateral cutaneous branch arises along the midaxillary line. It divides into anterior and posterior branches.

4. The nerve keeps giving muscular, perioseal and branches to the costal pleura during its course.

5. Anterior cutaneous branch is the terminal branch of the nerve.

ATYPICAL INTERCOOSTAL NERVES ~

The thoracic spinal nerves which do not follow absolutely thoracic course are designated as atypical intercostal nerves. Thus Intercostal one, two, are atypical as these two nerves partly supply the upper limb.

The first thoracic nerve entirely joins the brachial plexus as its last rami or root. It gives no contribution to the first intercostal space. That is why the nerve supply of skin of first intercostal space is from the supraclavicular nerves (C3, C4).

The second thoracic or second intercostal nerve runs in the second intercostal space. But its lateral cutaneous branch as intercostobrachial nerve is rather big and it supplies skin of the axilla as well. Third to sixth intercostal nerves are typical.

Also seventh, eighth, ninth, tenth, eleventh intercostal nerves are atypical, as these course partly through thoracic wall and partly through anterolateral abdominal wall. Lastly the twelfth thoracic is known as subcostal nerve. It also passes through the anterolateral abdominal muscles. These will be further sthHipti in Vnlnmp 9, of this hnnk .

CLINICOANATOMICAL PROBLEMS

1. An adult man was stabbed on his upper left side of chest. He was taken to the casualty department of the hospital. The casualty physician noted that the stab wound was in left third intercostal space close to the sternum. Further the patient has engorged veins on the neck and face.

Clinicoanatomical problems:
? What is the site of injury?
? Why are the veins of the neck and face engorged?
? What procedure would be done as an emergency measure before taking him to operation theatre?

Ans. The injury is in left third intercostal space injuring the pericardium and right ventricle, causing haemopericardium. Veins of the neck and face are engorged as the venae cavae are not able to pour blood in the right atrium. Pericardial tapping is done to take out the blood from the pericardial cavity. It is done as an emergency measure.

2. A 40-year-old lady while playing tennis, suddenly fell down, holding on to her chest and left arm due to severe pain.

Clinicoanatomical problems:
? Why is the pain in her chest?
? Why is the pain in her left arm?

Ans. Tennis is a very strenuous game. The lady fainted as there was more need for the oxygen. Since it could not be supplied, the myocardium got ischaemic which caused visceral pain. The pain is carried by afferents which travel mostly with left side sympathetic nerves to the thoracic one and thoracic 2-5 segments of the spinal cord. Since somatic nerves (T1-T5) also travel to the same segments, the pain is referred to the skin area. T1 supplies the medial side of arm and T2-T5 supply the intercostal spaces.

3. A 10-year-old boy had mild cough and fever. The physician could feel the increased rate of his pulse, but could not hear the heart beat on the left side of his chest. After some thought the physician was able to feel the heart beat as well.

Clinicoanatomical problems:
? Where is the normal apex beat heart?
? Name the congenital anomaly of the heart which could cause inability of heart beat to be felt on the left side.
Ans. Apex beat is normally heard in the left fifth intercostal space, 9 cm from midsternal line, within the left lateral line. The congenital anomaly in this case is dextrocardia, when the heart is placed on the right side of the heart. The apex beat is heard in right fifth intercostal space to the right of the inferior end of the sternum.

4. A 45-year-old man complained of severe cough, loss of weight, alteration of his voice. He has been smoking for last 25 years. Radiograph of the chest followed by biopsy revealed bronchogenic carcinoma in the left upper lobe of the lung.

Clinicoanatomical problems:
? Where did the cancer cells metastasize?
? What caused alteration is his voice?

Ans. The bronchogenic carcinoma spread to the left bronchomediastinal lymph nodes. The left supraclavicular nodes are also enlarged and palpable; so these are called 'sentinal nodes'. The enlarged bronchomediastinal lymph nodes exert pressure on the left recurrent laryngeal nerve in the thorax causing alteration of voice. The cancer of lung is mostly due to heavy smoking.

5. A teenage girl was complaining of breathlessness. The physician heard a 'machine-like' murmur during auscultation on the second left intercostal space, close to the margin of sternum. There was continuous thrill on the same site. On getting radiographs of the chest and angiocardiography, a diagnosis of patent ductus arteriosus was made.

Clinicoanatomical problems:
? What is the 'machine-like' murmur?
? How can the shunting of blood prevented?
? Describe briefly the function of ductus arteriosus during prenatal life. When does it close?

Ans. The ductus arteriosus is a patent channel during fetal life for conducting the blood from left pulmonary artery to arch of aorta beyond the origin of left subclavian artery. This is necessary as lungs are not functioning. After birth, with the functioning of lungs, ductus arteriosus obliterates and becomes ligamentum arteriosum. If this does not take place, as occurs in one out of 3000 births, there is back flow of blood from aorta into pulmonary artery, giving rise to 'machine-like murmur'. Its treatment is surgical.
8. Which of the following veins is a direct tributary of superior vena cava.
   a. Hemiazygos vein
   b. Right superior intercostal vein
   c. Right bronchial vein
   d. Azygos vein

9. All the following statements are true about 'right principal bronchus' except:
   a. It is more in line with trachea
   b. It is wider than left principal bronchus
   c. It is longer than left principal bronchus
   d. The inhaled particles tend to pass more to the right bronchus

10. Which of the following does not open into the right atrium
    a. Anterior cardiac vein
    b. Small cardiac vein
    c. Coronary sinus
    d. Venae cordis minimi

B. Match the following on the left side with their appropriate answers on the right side.

11. Arteries and their branches:
    a. Internal thoracic i. Posterior interventricular
    b. Descending aorta ii. Posterior intercostal
    c. Right coronary iii. Anterior interventricular
    d. Left coronary iv. Anterior intercostal

12. Ribs:
    a. True ribs i. 8th, 9th and 10th
    b. Atypical ribs ii. 1st, 11th, 12th
    c. Least fractured ribs iii. 1st - 7th
    d. Vertebrochondral ribs iv. 1st, 2nd, 10th, 12th

13. Vertebral levels:
    a. Aortic opening in i. T8
       diaphragm
    b. Oesophageal opening in ii. T10
       diaphragm
    c. Inferior vena caval opening iii. T11
       in diaphragm
    d. Gastro-oesophageal iv. T12
       junction

14. Mediastinum:
    a. Anterior mediastinum i. Trachea
    b. Middle mediastinum ii. Azygos vein
    c. Posterior mediastinum iii. Heart
    d. Superior mediastinum iv. Sternotomochordal

C. For each of the incomplete statements or questions below, one or more answers given is/ are correct.
   Select
   A. If only 1, 2, and 3 are correct
   B. If only 1, 3 are correct
   C. If only 2, 4 are correct
   D. If only '4' is correct
   E. If all are correct

15. The apex of the heart:
    1. Is formed only by left ventricle
    2. Is situated in the 4th intercostal space
    3. Is just medial to midclavicular line
    4. Is directed downwards, backwards and to the left

16. The aortic opening in the diaphragm:
    1. Lies at the lower border of 12th thoracic vertebra
    2. Lies in the central tendinous part of the diaphragm
    3. Transmits aorta, thoracic duct and azygos vein
    4. Is quadrangular in shape

17. The trachea
    1. Extends in cadaver from C6 to T4.
    2. Deviates to the right at its termination
    3. Is lined by ciliated pseudostratified epithelium
    4. Is seen as a vertical radiopaque shadow in radiograph.

18. Thoracic duct
    1. Begins at the lower border of LI.
    2. Is the upward continuation of cisterna chyli
    3. Enters the thorax through vena cava opening in the diaphragm
    4. Ends by opening at the junction of left subclavian and left internal jugular veins.

    1. Is aerated by a segmental bronchus
    2. Is pyramidal in shape with its base directed towards hilum
    3. Is an independent respiratory unit
    4. Is supplied by its own separate branch of pulmonary artery and vein

20. Visceral pleura
    1. Is pain insensitive
    2. Develops from splanchnopleura.
    3. Covers all the surfaces of the lung including fissures but not the hilum
    4. Is innervated by autonomic nerves
